Contaminated rainwater and, in particular, pathways of exposure to surface water via sewage treatment plant bypass and separated rainwater systems, are increasingly considered within Biocidal risk assessments. A first tier approach was designed for outdoor application of a number of preservative products (UBA, 2014) and there is indication that other product types may be considered in the future. In addition, an existing higher tier approach involving the HardSpec model is commonly used for plant protection products applied in urban areas and it is proposed that the data generated for the design of this model could be the basis for a second tier approach for biocides. Particular consideration is given to those substances exhibiting a strong potential for dissipation and to those uses where infiltration and retention may be significant.

In silico Prediction of the Formation of Non-Extractable Residues (NER) in Soil with Regard to their Environmental Hazard

R. Kühne, Helmholtz centre for environmental research - UFZ / Department of Ecological Chemistry; A. Miltner, Helmholtz Centre for Environmental Research UFZ / Department of Environmental Biotechnology; K. Nowak, RWTH Aachen University / Institute for Environmental Research Biology V; M. Kästner, Helmholtz centre for environmental research - UFZ / Department of Environmental Biotechnology; N. Ost, Helmholtz Centre for Environmental Research UFZ / Department of Ecological Chemistry; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; G. Schüürmann, Helmholtz centre for environmental research - UFZ / Department of Ecological Chemistry

Organo-clay complexes are the major sink for xenobiotics in soils and sediments. Pollutants can be degraded and transformed by biotic and abiotic mechanisms. Additionally, the parent xenobiotics and their transformation products are immobilized as non-extractable residues (NER). All chemicals are assumed to form NER to different extents, but the actual amount of NER formation depends not only on the chemical structure but also on the environmental conditions. Three types of NER have recently been classified: Type I are xenobiotics sorbed or entrapped, type II are xenobiotics covalently bound, and type III are biogenic residues. The possible remobilisation of incorporated xenobiotics is of environmental concern and refers particularly to type I NER. Type II or type III NER formation is considered not to cause harm. We therefore launched a project aiming at predicting the potential for formation of different types of both xenobiotic and biogenic NER formation from xenobiotics, in particular pesticides. To this end, derivation of respective structural alerts had been envisaged originally. However, we found that the available experimental data are not sufficient to derive general structural alerts. Structural alerts thus can only address a subset of potential NER forming chemicals. Acknowledging this restriction, the strategy has been altered and now focuses on identifying appropriate thresholds of physicochemical and molecular properties and their control on NER formation. The paper provides an overview of the original and adapted approach and reports modelling results. The financial support of this study by CEFI-LRI (ECO24-UFZ) is gratefully acknowledged.

Kinetic Evaluation of Field Dissipation Studies: Applying MCMC simulator DREAM for Parameter Inference and Uncertainty Analysis

S. Sittig, EFate Modelling; Z. Gao, Tier 3 Solutions GmbH; G. Reinken, Bayer CropScience AG; G. Goerlitz, Bayer CropScience AG / Environmental Safety

In legacy field dissipation studies, plant protection products (PPP) were applied to soil surface or to cropped plots. Consequently, surface processes other than (microbial) degradation might contribute to the overall dissipation of PPP mass in a soil profile. The properties of the compound as well as agro-climatic conditions will influence degradation, plant uptake and leaching below the lowest sampling depth, particularly if the depth of sampling is limited. A recent EFSA guidance document [1] provides criteria to be followed to determine a true DegT50 from those field trials. The guidance is lacking some information about the detailed procedure to derive DegT50 of metabolites, particularly if global solvers or inverse modelling approaches are to be considered. This presentation describes a novel methology to derive the true DegT50 of a primary metabolite from legacy field studies employing a global solver. The evaluation considers requirements of latest regulations, i.e. ignoring masses before 10 mm of rainfall, and using state of the art weather data. For an improved understanding of the results of field dissipation studies the leaching model PEARL 4.4.4 was coupled with a Markov Chain Monte Carlo sampler (Differential Evolution Adaptive Metropolis algorithm, DREAM_ZS)[2] to efficiently search the parameter space of the advective-dispersion model. Standard statistical measures according to FOCUS are given, e.g. Chi-square test and an analogon of t-test statistics. This overall procedure allowed for a representation of the distinct processes occurring under field conditions, i.e. degradation, leaching, plant uptake (in cases of cropped trials). Consequently, in legacy studies a true DegT50 can be estimated other than an overall DT50, employing a standard time-step normalisation procedure. We will present the results of field trial experiments along with an analysis of parameter uncertainty. [1] EFSA (2014): *EFSA Guidance Document for evaluating laboratory and field dissipation studies to obtain DegT50 values of active substances of plant protection products and transformation products of these active substances in soil*.European Food Safety Authority. MO243

Estimation of degradation rates of pesticides in surface water from higher-tier effect cosm studies by inverse modelling with TOXSWA

J. Boesten, Alterra / ERA team; P.I. Adriaanse, Alterra Wageningen University and Research Centre / ERA team; J.W. Deneer, Alterra Wageningen UR / ERA team; C.v. Griethuysen, Board for the Authorisation of Plant Protection Products and Biocides

In water bodies with low flow velocities or with multiple spray drift deposition events, exposure concentrations of pesticides are influenced by their degradation rate in water. $DegT_{50,water}$ values derived from water-sediment studies do often not represent well degradation rates in water in realistic, outdoor cosm systems. Therefore, we developed a method to estimate degradation rates in water from available higher-tier effect cosm studies (which have often limited fate data).Results obtained with this method can be useful in higher tier exposure assessment for authorization purposes of pesticides on a national and zonal level. We derived $DegT_{50,water}$ values from outdoor cosm studies for three compounds with relatively low K_{oc} values (metribuzin, linuron and imidacloprid). In total eight outdoor studies were analysed. Studies were only included if aqueous concentrations were available for at least five sampling times and if the water depth was reported. Concentrations in the sediment were not used for the fit (available for only one of the studies). We minimized the difference between simulated and measured aqueous concentrations using PEST vs 13.0 and running FOCUS_TOXSWA_4.4.2 many times. The quality of the fits was assessed visually (considering also trends in residuals) and by calculating the error level of the χ^2 test as recommended by FOCUS Degradation Kinetics. All fits were found to be visually acceptable. The χ^2 error of the eight studies ranged from 7 to 20% and was on average 11%. The 95th confidence interval of the $DegT_{50,water}$ ranged typically from 75 to 125% of the fitted $DegT_{50,water}$ value. Thus, the estimation procedure resulted in sufficiently accurate $DegT_{50,water}$ values for all eight outdoor higher-tier effect cosm studies. For all eight studies, the $DegT_{50,water}$ values obtained appeared to be shorter than those derived from hydrolysis and water-sediment studies (the difference was typically an order of magnitude and at least a factor of two). \n \n

MO244
VFSmod - A comparison with field derived values of pesticide removal efficiency under controlled conditions
T. Pepper, S. Taylor, G. Hughes, Cambridge Environmental Assessments
Consideration of the pesticide removal efficiency of vegetative filter strips (VFS) within the regulatory process has been through the use of standardised values for buffer strips of set classes of width (10-12m and 18-20m) and adsorption (aqueous and sediment associated). These are applied to all compounds for all FOCUS scenarios, all crops and all usage periods. The adoption and usage of more dynamic models, such as VFSmod, by Member State regulatory authorities has been relatively slow, despite efforts to underpin this model with a wide database of field data, improve model parametrisation, and further align scenario development with existing FOCUS frameworks. As a complimentary approach to the use of VSFmod, and in support of a number of regulatory submissions, a series of replicated field studies have been carried out as part of the data package where the efficiency of VFS for specific compounds and specific VFS widths has been tested under controlled conditions representative of a selected worst case FOCUSsw scenario covering the intended use profile. This study explores these FOCUSsw scenario related experimental VFS data with a view to examining VFSmod performance further and potentially expanding the validation dataset that underpins it.

MO245
Spray Drift: Representation, Mitigation and Future Directions
G. Azimonti, ICPS; A. Chapple, Bayer Crop Science AG; N. Mackay, DuPont UK Ltd. / Environmental Modelling; P. Miller, Independent Consultant; K.M. Nienstedt, European Commission - DG SANCO / PPR; C. Pickl, German Environment Agency; T. Wolf, AgriMetrix Research and Training
Spray drift measurements are used to assess the applied spray volume carried downwind from application and deposited on adjacent surfaces. Evaluation reference conditions are detailed in ISO 22866 but allow some variation in environmental characteristics at point of application (wind speed, temperature, humidity), application settings (nozzle height, travel speed), crop and landscape influences (bare ground / grass *versus* crop, choice of crop) and measurement standards (choice of collector, relationship of measurement to edge of field / end nozzle location). As a consequence, drift trials may provide variable drift representations. SETAC MAGPIE WG concluded that consideration of harmonization of testing standards beyond ISO 22866 would be better addressed independently *via* spray physics expert working groups. To improve understanding of spray drift and the regulatory basis for risk assessment, a SETAC workshop (DRAW) is underway to facilitate efforts in a number of areas. - Assemble a database of existing spray drift trials for boom sprayers - Analyse and interpret available data; highlight areas where protocol-derived differences warrant further targeted trial investigations - Develop targeted trials to quantify differences emerging from measurement methodology and choices - Develop proposals for standardized measurements to investigate key drivers or influences on drift - Support further interpretation of existing spray drift trials - Determine which collector type best represents the actual deposition capture by the relevant risk assessment compartment - Develop mathematical modelling as a higher-tier basis for risk assessment refinement The valuable heritage of research on spray drift must be harnessed for the longer-term goal of facilitating greater flexibility with drift representation through mathematical modelling of drift arising from boom applications. As representation of spray drift affects a range of risk assessments (aquatic, non-target arthropods/terrestrial plants *etc*.), the workshop includes consideration of implications for these assessments. A specific work group has been developed to provide European regulatory authorities with an expanded, secure toolbox of risk mitigation measures. This action will enable efficient transition to a new framework of drift representation coupled with options to accommodate change.

MO246
Research of boscalid and markers of exposure to boscalid in honey bees
G. Daniele, C. Jabot, B. Giroud, Institut des Sciences Analytiques / TRACES Team; L. Belzunces, INRA / Umr Abeilles Environnement; E. Vulliet, CNRS / TRACES Team
The intensification of agriculture has been characterized in last decades by a significant use of pesticides. To protect bees against their effects, it is necessary to develop analytical tools for the detection of these compounds in bee products and in bees. The search for pesticides in bee generally involves native target substances. However they may have been degraded or metabolized by bees or due to delayed mortality findings; thus the parent compound may no longer be detectable in the bee. Evidence of contact between bee and pesticide may, nevertheless, be obtained by detecting metabolites/markers of exposure. However, the study of metabolites and of their toxicity, in the bee is still undeveloped. The reasons are firstly, the lack of information on the nature of the metabolites, and secondly the lack of analytical standards, which are essential for conducting the tests. Our work is part of this context and aims firstly at characterizing metabolites of boscalid in bees, and next to search them into bees from symptomatic colonies. Boscalid was chosen for this study as it is a new-generation fungicide which use is increasing, it has a broad spectrum of activity, and it has been detected in bee matrices. Honeybees were sprayed with boscalid in a Potter spray tower and left in crates 24 h at 28°C before being frozen to stop metabolism. Boscalid and its metabolites were extracted from bees by QuEChERS method prior to analysis by liquid chromatography coupled to high resolution mass spectrometry (LC-Q-TOF). Metabolites research was performed by comparing the retention time and mass/charge ratio between sprayed bees and control ones. Discriminant masses (exact mass, isotopic profile, mass fragments) and empirical formula next obtained were compared with databases and/or in silico fragmentation. Thus 5 markers of exposure to boscalid were determined. Then they were synthesized and quantified in bee samples collected from various beehives located in France. The analysis of boscalid and the 5 identified markers of exposure was performed on 42 bee samples from symptomatic colonies. Among these markers, 4 were present in the samples (levels comprised between 0.2 and 36.3 ng/g). About half samples were positive for at least one of the 6 target molecules whereas boscalid was detected in 11 samples but quantified in only 4 with levels up to 330 ng/g. These results highlight the importance of not limiting the analysis of the parent drug in sentinel organisms such as bees.

Prospective and retrospective soil risk assessment of chemical stressors (P)

MO247
How to deal with different soil organic matter contents in ecotoxicological studies for the risk assessment of soil organisms?
P. Kotschik, Umweltbundesamt / Federal Agency of Environment / Risk assessment for plant protection products; S. Pieper, German Federal Environment Agency (UBA) / Plant Protection Products; S.E. Egerer, D. Felsmann, Umweltbundesamt / Federal Agency of Environment Germany; B. Scholz-Starke, RWTH Aachen University, Institute for Environmental Research / Institute for Environmental Research BioV
The risk assessment for non-target soil meso- and macroorganisms is based on ecotoxicological tests performed in standardized test soils as a first step. Depending on the test organisms, the guideline recommendations regarding the soil organic matter content (OM) of the test soil vary. For earthworms, the OECD Guidelines 207 and 222 recommend 10% OM (as peat) for the composition of the artificial test soil. The OECD Guidelines 226 and 232, targeting chronic effects on mites and collembolans, propose a soil OM (peat) content of 5%. The quantity and quality of OM in soils might exert a strong effect on the sorption and bioavailability of tested substances and therefore alter the determined toxicity of the tested compound. Amount and quality of OM used in tests with artificial soil might strongly diverge from the humic materials in natural agricultural soils. EFSA (2012) reports e.g. for the Central Zone of Europe OM contents between 1.8 and 8.6% (10th and 90th percentiles of the distribution), respectively. This adds to the uncertainties accompanying the extrapolation of toxicity endpoints measured under standard laboratory test conditions to the situation in the field. To account for the effects of OM content on sorption and thereby bioavailability of tested compounds, the current Guidance document (GD) on Terrestrial Ecotoxicology SANCO/10329/2002 (European Commission 2002) recommends a reduction factor of two for ecotoxicological endpoints derived from studies with lipophilic substances (defined by a $\log K_{ow} > 2$) in artificial soils with 10% OM. At the time the current GD was established, tests with soil organisms were conducted with 10% OM as peat in the soils exclusively. The OECD guidelines 226 and 232 were adopted later, and therefore no proposal exists in the current GD, how to deal with toxicity endpoints for soil organisms derived from tests with 5% OM. Currently, the risk assessment scheme for soil organisms deals similarly with

endpoints conducted in test soils with different peat contents. This contribution presents the outcome of a comprehensive analysis of all available test data with soil organisms in artificial soils of different OM contents that were submitted to authorities in the framework of PPP registration or active substance evaluation. Moreover, it reviews available literature on compound toxicity for soil organisms in soils of different properties, with a focus on the effects of different soil OM contents.

Soil enzyme activities reveal re-functionalization of trace metal agricultural contaminated soils after Miscanthus giganteus plantation

N. CHEVIRON, INRA/AgroParisTech / UMR ECOSYS Plateforme BiochemEnv; C. Marrauld, I. Lamy, INRA Institut National de la Recherche Agronomique / UMR ECOSYS

Context The use of contaminated soils for non-alimentary cultures is gaining importance in view of the scarcity of agricultural surfaces and the presence of some potential harmful pollutants in surface horizons that could impact the food chain. But in the case of trace metal contaminated soils few information are available on the effects of land use and soil management changes on soil quality parameters and/or soil health. Suggestion was made in literature that enzymatic activities could be good indictors of soil functioning, providing special attention to confounding effects. In this work the objective was to assess the impact of change of cultural practices on the soil quality, as seen by soil enzyme activities. **Materials and methods** We used trial essays were contaminated parcels were divided in two, one part was left under annual culture and the other was planted with the high biomass plant *Miscanthus giganteus*. The enzymatic activities of the C and N cycle were investigated with a diachronic follow-up of β-glucosidase and urease activities, quantified on fresh soil triplicates using colorimetric methods and microplate assay. The effect of miscanthus plantation was also followed up in a soil profile. Soil samples were collected in spring from 2009 to 2011 at 0-10 cm in a trace metal contaminated site with an organic origin of pollution. Sampling in the soil profile was done every 10 cm in depth until 50 cm. **Results** Results for the diachronic follow up in surface horizons showed that soil urease activities under miscanthus differ clearly from those under annual culture with higher values under perennial culture. This was particularly observed as the setting-up of miscanthus was former. β-Glucosidase activities, while less indicative, also suggested an enhancement of microbial activities under miscanthus. When normalizing with the enzymatic activities of the parcel under annual culture, results clearly show the effect of the plantation duration on the re-functionalization of the soil. But despite the rapid answer of the indicators, three years were necessary to significantly quantify an evolution. N cycle was more sensible to point out the re-functionalization of the contaminated soil. In the soil profile results of the enzymatic activities under miscanthus highlighted the evolutionary structuration of microorganisms in contaminated soil. This evolution was faster near the soil surface than in subsurface horizons and better assessed for N cycle.

MO249

Gaining a better understanding of toxic effects on soil communities, using the example of AgNP

M. McKee, A. Paa, University of Bremen / Center for Environmental Research and Sustainable Technology UFT; S. Chelinho, University of Coimbra / Department of Life Sciences of University of Coimbra; J.F. Sousa, University of Coimbra / Dept Life Sciences of University of Coimbra; J. Filser, University of Bremen

Resource limitations and ethical concerns often hinder field studies in ecotoxicology. One way to meet the frequent calls within the scientific community to increase ecological realism of ecotoxicological test systems is the use of test systems at an intermediate ecological organizational level; this was applied in the present study. Silver nanoparticles (AgNP) were used as an exemplary test system because of their expected accumulation in soils. Ecotoxicological information on this emerging technology for soil communities is still sparse. A trait-based approach of morphotyping the Collembola community (Chelinho et al. 2013) was applied to enable an extrapolation of the gained results to other soil communities. A natural microarthropod community from a meadow with sandy acidic soil in northern Germany was extracted and introduced to AgNP (10 μg/ kg, 10 mg/ kg) and $AgNO_3$ (10 μg/ kg) contaminated OECD soil. The test was run for 6 weeks under standardized laboratory conditions (12:12 light: dark, 15° C). The experiment was repeated with the same community and changed OECD soil composition to assess how clay and sand content affect the toxicity of AgNP and $AgNO_3$. First results show that the dominant groups of hemiedaphic and euedaphic Collembola and mites benefited from low AgNP concentrations, most probably due to their antimicrobial characteristics which kill off microbes harmful to microarthropods. Higher AgNP concentrations and low $AgNO_3$ concentrations were however harmful to Collembola and mites compared to the control. $AgNO_3$ is therefore more toxic for the dominant groups of microarthropods than AgNP. The number of Collembola individuals and morphospecies was lower after the test than in the initial community. This shows that either the extraction procedure or the change of soil conditions is too stressful for several rare Collembola morphotypes. Mites, dominated by Oribatida, showed a low recovery rate in the control compared to the initial community, indicating that the OECD soil does not offer optimal conditions for mites to thrive. This might be due to the lack of microbial food in the artificial soil. The data analysis of the community test with adjusted OECD soil will be set in comparison to the described results. Currently the same experimental design with OECD soil is being applied to two additional soil communities to assess the impact of AgNP and $AgNO_3$ on additional morphospecies of Collembola and to further validate the methodology.

MO250

A comparison of functional and structural soil testing for risk assessment of plant protection products

A. Dinter, DuPont de Nemours (Deutschland) GmbH / Crop Protection; S. Loutseti, DuPont De Nemour Hellas S.A.; A. Samel, DuPont Crop Protection / Ecotoxicology

In the development process of a new active substance of a plant protection product (PPP), an insecticide, functional tests and structural tests were performed, which allows a comprehensive assessment of effects on functional and structural soil parameters. In the functional field study – a test on the breakdown of organic matter following OECD GD 56 (2006) and EPFES WS recommendations (2002) – slight transient effects due to the insecticide were found on mass loss of organic matter at 1 month after treatment, while at 3 and 6 months after treatment no significant impact on organic matter decomposition was found. The potential effects of the test substance on structural parameter (soil mites, and collembolans for which a potential risk was identified based on worst-case laboratory testing) were addressed via additional soil samplings and organisms extraction on the same plots of the organic matter breakdown study. Samplings performed at 3 and 5 months after treatment indicated no significant effects on the structural parameters (soil mites and collembolans). In another field study – including higher tested insecticide soil concentrations – with focus on the structure of Collembola populations showed some initial transient effects, but also no longer term impact. On the basis of these results it can be concluded that the functional field test on organic matter breakdown is sensitive and covers the effects on soil mites and Collembola. Sensitivity and initial effects in field tests on organic matter breakdown were also reported in a previous industry-wide ECPA review of such data (Dinter et al 2008). It is concluded that functional test system on organic matter breakdown is sensitive and covering potential effects on soil non-target meso- und macrofauna and considered – due to the direct link to protection goals derived from the EsS concept (plus the robustness of the test conduct itself) a superior testing tool for soil risk assessment of plant protection products.

MO251

Making soil protection goals based on the ecosystem services concept operational in ecotoxicological risk assessments

P. Kabouw, BASF SE

What, where, and when to protect are fundamental questions that need to be addressed before designing environmental risk assessment (ERA)schemes. The ecosystem services (EsS) concept can give guidance in what to protect for ERA schemes. Here we use the EsS concept to propose a novel and science based soil risk assessment for PPPs. As a first step we define registration principles followed by identification of soil relevant EsS as a second step. Thereafter, we formulate relevant protection goals (PGs) which are transferred into test systems. Finally our goal will be to define a tiered ERA based on acceptability criteria. The registration principles we identified were that ERA should be workable, scientifically sound and politically acceptable. A well-structured ERA should follow a tiered approach, reduce uncertainties and data gaps concerning organism potentially at risk. A ERA scheme should use validated test systems only, needs to have conservative trigger values, and needs clear acceptability criteria. Soil relevant EsS (e.g. nutrient cycling) can be affected by PPPs. While it is relatively easy to define general PGs, it can be quite challenging to define specific PGs. In the soil area the current focus is on structural PGs (testing of surrogate species) and lacks a clear link to PGs derived from EsS. On the other hand functional PGs directly correlate to EsS. Thus suitable tests based on functional parameters will reduce uncertainties with regard to EsS. Although several functional tests are already available a critical evaluation is needed to select representative and sensitive test systems. Additionally, these novel functional tests need to be linked to information obtained in structural tests for the final risk assessment. The EsS and related PGs might be weighted differently on a spatial scale in agricultural landscapes. For in-crop areas functional aspects are in focus (e.g. food production & nutrient cycling) whereas in off-crop areas structural aspects are additionally of interest. Ecosystem services and the PGs derived from them are suitable to design a new soil ERA scheme. Several EsS are relevant to soil and can be affected by PPPs. Ongoing research will help to define a workable ERA scheme for soil that combines structural and functional endpoints. PGs based on EsS should be addressed by validated and suitable functional tests as these in contrast to structural tests directly link to PGs and thus fulfil registration principles.

MO252

Statistical Power and MDDs in Earthworm field testing

T. Vollmer, Eurofins Agroscience Services Ecotox GmbH / Field Ecotoxicology; S. Knaebe, Eurofins Agroscience Services Ecotox GmbH / Ecotoxicology Field; S. Frank, Eurofins Agroscience Services Ecotox GmbH; O. Klein, Eurofins

Agroscience Services Ecotox GmbH / Ecotoxicology Field
Earthworm field tests are carried out as part of the risk assessment of plant protection products according to the ISO guideline 11268-3 (ISO 2014). This document provides information on experimental design, test site requirements, data assessment and validity criteria of the test, but does not give indications about the required statistical power of the test or about the effect size that should be detectable in such a field study. In contrast to that, the guidance for summarizing earthworm field studies published by the National Institute for Public Health and the Environment of the Netherlands (De Jong et al., 2006) demands that the minimum effect level that could be detected as statistically significant in a study should be reported. For aquatic test systems, it has been suggested (EFSA, 2013 and Brock et al., 2015) to use the minimum detectable difference (MDD) to evaluate the statistical power of aquatic test systems. In order to provide a better understanding of the earthworm field test we carried out a retrospective power analysis of a series of earthworm field studies covering a range of land uses and soil and climatic conditions using the MDD concept. MDDs will be presented for the overall earthworm population as well as for individual taxa and for ecological groups. The impact of site related (size of the earthworm population, homogeneity of earthworm distribution across the test site) and study design related criteria (e.g. number of replicates) on the statistical power in terms of MDD will be discussed. **Brock TCM, Hammers-Wirtz M, Hommen U, et al., 2015. The minimum detectable difference (MDD) and the interpretation of treatment-related effects of pesticides in experimental ecosystems. Environmental Science and Pollution Research International 22(2): 1160-1174. doi:10.1007/s11356-014-3398-2. Guidance on the determination of effects in field situations.**

MO253

Soil functional test systems for an in-field soil risk assessment of plant protection products

G. Ernst, Bayer CropScience AG / Ecotoxicology; J. Bendall, Dow Agrosciences; M. Coulson, Syngenta; B. Garlej, ADAMA; P. Kabouw, BASF SE; S. Loutseti, DuPont De Nemour Hellas S.A.; A. Sharples, Cheminova A/S
Soil functional test systems provide valuable and ecologically relevant information for the risk assessment of plant protection products. Functional tests directly measure ecosystem functions and services which are provided by soils and soil organisms (e.g. organic matter degradation and mineralization). Focusing on structural endpoints in the risk assessment for plant protection products lacks a clear link to the protection goals derived from ecosystem services. Directly measuring soil functions and services can help to better assess the impact of a stressor on the fertility of soils. Furthermore, functional test systems can help to evaluate the ecological relevance of a density change of a soil organism population affected by a certain stressor. In order to improve the current toolbox for the soil risk assessment, a project on soil functional test systems was initiated by the European Crop Protection Association in 2014. In a first step a literature search identified several promising functional test systems which could provide valuable and ecologically relevant information. In a second step a field study was set up in 2015 which measures the impact of two insecticides (Methamidophos, Lindane) on organic matter degradation (minicontainer, bait lamina, litterbag test). Soil micro-arthropod abundances are monitored in parallel to determine the link between effects on the structure of soil micro-arthropods and their soil functional implications (i.e. organic matter breakdown). In this study the suitability of the different functional test systems related to organic matter degradation is evaluated with regard to their potential use in soil risk assessment of plant protection products. The functional test systems (i.e. the minicontainer test) show overall consistent and reproducible results in the field trial. The results indicate that the process of organic matter degradation is dominated by soil microbes. Soil mesofauna contributed only to minor extend to organic matter degradation. Thus, the minicontainer test did not show a clear effect of insecticides on the mesofauna driven organic matter degradation although abundances of Collembola and Acari were heavily reduced by the insecticide applications. Thus, the relevance of structural endpoints on soil micro-arthropods (population/community level) within an in-field soil risk assessment for plant protection products which focus on maintenance of soil fertility (protection of soil functions) is questionable.

Evaluation of epoxiconazole bioavailability in soil to the earthworm Aporrectodea icterica

S. Nélieu, G. Delarue, INRA Institut National de la Recherche Agronomique / UMR ECOSYS; E. Ollivier, INRA Institut National de la Recherche Agronomique / UMR ECOSYS Platform BiochemEnv; P. Awad, INRA Institut National de la Recherche Agronomique / UMR ECOSYS; C. Mougin, INRA (Institut National de la Recherche Agronomiqu / UMR ECOSYS; C. Pelosi, INRA Institut National de la Recherche Agronomique / UMR ECOSYS
In soil, the determination of total concentration using an exhaustive extraction method is not relevant to evaluate the exposure of an organism to a chemical, because of sorption processes. However, little attention has been paid to the bioavailability of organic contaminants to earthworms, and to their effect on sensitive earthworm species found in cultivated fields, such as *Aporrectodea icterica* [1]. As ecosystem engineers, earthworms influence soil structure and chemistry and are thus key-organisms for the health of terrestrial ecosystems. However, they can be threatened by contaminants such as the fungicide epoxiconazole, which is persistent in soil and presents a chronic toxicity even towards a resistant earthworm species (*Eisenia fetida*) at a concentration close to the recommended dose. This study aimed to propose a mild extraction method to evaluate the bioavailability of the fungicide epoxiconazole to the earthworm *Aporrectodea icterica* [2]. Experiments were conducted in soils presenting various textures and organic carbon contents, spiked with formulated epoxiconazole 7 to 56 days prior to their extraction at one-fold to ten-fold the recommended dose. In parallel, the epoxiconazole concentration was determined in exposed earthworms. All the analysis were performed by UHPLC-MS/MS. The fungicide's effects were evaluated by measuring weight gain, enzymatic activities and total protein contents. The proposed method to evaluate bioavailability was based on the pesticide entrapment in the cavity of hydroxypropyl-β-cyclodextrin, thus fulfilling the criteria of the ISO 17402 norm [3]. Furthermore, this mild method was demonstrated to be sensitive to soil sorption capacities and to ageing. The mild extraction method was then applied to explore the relationship between total and bioavailable concentrations in soil and in *A. icterica*, over 7 or 28 days exposure time. This demonstrated the proportionality between epoxiconazole concentration in earthworm and available in soil (up to 96%, with regression coefficient R^2 0.98). Sublethal effects on earthworm remained not significant. **References** 1. C. Pelosi, S. Joimel, D. Makowski, 2013. Chemosphere 90, 895-900 2. S. Nélieu, G. Delarue, E. Ollivier, P. Awad, F. Ecotoxicological assessment of chemical fumigants utilising an earthworm bioassay (Eisenia andrei) and soil microbial communities

M. Maboeta, North West University / Unit for Environmental Sciences and Management; T. Fouche, S. Claassens, North-West University
Fumigation is an important crop protection practice to control agricultural crop pathogens and diseases. Methyl bromide (MeBr) and it success as nematocide since the 1940's is well documented. It has, however, been identified as ozone depleting gas and it was to be phased out by 2005 under the Montreal Protocol (2002). The more common alternatives to MeBr include metham sodium (MNa) and cadusafos but very little information is available about their effects on non-target and beneficial soil organisms. The aim of the study was to determine the ecotoxicity of MNa and cadusafos utilising a standardised earthworm (*Eisenia andrei*) ecotoxicity test (OECD 2004). In addition to this the genotoxicity of MNa and cadusafos was assessed by investigating DNA damage (comet assay) of individual earthworm cells. Further, to assess changes in the microbial community function and structure by means of Biolog™ Ecoplates and phospholipid fatty acid (PLFA) analysis after treatment of soil with chemical fumigants. The chemical fumigants had a marked negative impact on the survival, growth, reproduction and the genotoxicity of the earthworms with MNa causing greater harm than cadusafos. The effects on the microbial community varied. Both chemicals had an inhibitory effect on the microbial growth in terms of the viable biomass determined by PLFA and the average well colour development in the Biolog™ Ecoplates. No lasting effects were observed in the community structure. Overall, cadusafos had a more pronounced effect on the microbial community functional diversity than MNa.

MO256

Application of Equilibrium partitioning-based model framework for evaluating soil and sediment hazards of lipophilic nonpolar organic substances

M. Leon Paumen, ExxonMobil Biomedical Sciences / ExxonMobil Biomedical Sciences TES Division; A.D. Redman, Exxon Mobil Biomedical Sciences / Toxicology and Environment Science Division; G.E. Bragin, ExxonMobil Biomedical Sciences, Inc. / Environmental Sciences Division; L.K. Low, ExxonMobil Biomedical Sciences / Toxicology Environmental Sciences Department
The target lipid model (TLM) is a QSAR framework used to predict acute and chronic toxicity of substances based on structure. This framework has been extended for calculation of predicted no effect concentrations (PNEC) of highly lipophilic hydrocarbon substances to support risk assessment activities of single chemicals as well as complex substances such as fuels, solvents, and lubricants. Recently, this framework was extended into soils and sediments using equilibrium partitioning (TLM-EqP) to support hazard evaluation, risk assessment, and read across activities thereby maximizing use of available data. The TLM-EqP

framework established the range of sensitivities for common test species (invertebrates, microbial endpoints, plants), which supports read across from the results of one assay to another. This framework was applied to recent dossier updates to address existing data gaps. The approach consisted of a weight of evidence built using TLM-EqP predictions and read across to available data, which allowed an improved experimental design for additional testing. This framework was used to establish the upper limit of the predicted porewater solubility (~100 mg/kg in bulk soil) to avoid potential formation of oily residues, which introduce the potential for physical oiling. While the mechanism of physical oiling could be a true hazard, predicted environmental concentrations in soil for most substances under typical use patterns are very low (< 0.01 mg/kg). Confirmatory testing in soil and sediment showed lack of toxicity consistent with model predictions and consistent with existing test data in water and soil. This framework promotes realism in chemical risk assessments by designing tests based on physicochemical properties and likely hazards of the test substance. This presentation will review the technical basis for the framework and illustrate the application of the methodology to available case studies, i.e. dossier updates to insoluble, nonpolar organic substances.

MO257

Effects of wheat seed dressings with neonicotinoid insecticides and fungicides on soil organisms

J.G. Zaller, N. König, A. Tiefenbacher, Y. Muraoka, University of Natural Resources and Life Sciences Vienna / Institute of Zoology; A. Ratzenböck, Austrian Agency for Health and Food Safety Ltd. Vienna / Institute for Seed and Propagating Material Phytosanitary Service and Apiculture; F. Baier, University of Natural Resources and Life Sciences Vienna / Institute of Zoology; M. Bonkowski, University of Cologne / Department of Terrestrial Ecology Institute of Zoology; R. Koller, Forschungszentrum Jülich GmbH / IBG Plant Sciences Institute for Bio and Geosciences

Seed dressing with pesticides is widely used to protect crop seeds from pest insects and fungal diseases. While there is mounting evidence that especially neonicotinoid seed dressings detrimentally affect pollinators, surprisingly little is known on potential side effects on soil biota. We hypothesized that soil organisms would be particularly susceptible to pesticide seed dressings as they get in direct contact with these chemicals. Using mesocosms with field soil we investigated, whether seeds treated either with neonicotinoid insecticides or fungicides influence the activity of earthworms, collembolan, protozoa and microorganisms. Additionally, we also examined interactions between soil organisms and seed dressings. The full-factorial design consisted of the factor seed dressing (control vs. insecticide vs. fungicide), earthworm (no earthworms vs. addition of *Lumbricus terrestris* L.) and Collembola (no Collembola vs. addition of *Sinella curviseta* Brook). We used wheat seed material (*Triticum aesticum* L. cf. Lukullus) available for farmers at a recommended seeding density of 367 m^{-2} (18 seeds per mesocosm). Seed dressings (particularly fungicides) increased Collembola surface activity, increased the number of protozoa and reduced soil decomposition rate but did not appear to affect earthworm activity. Earthworms decreased wheat growth, reduced soil basal respiration and microbial biomass but increased soil water content and electrical conductivity. Collembola increased earthworm surface activity but reduced soil basal respiration. Earthworms interactively affected effects of seed dressings on Collembola activity. We find it remarkable that the reported non-target effects of seed dressings on soil organisms were found after a one-time application of only 18 pesticide treated seeds. Because of the fundamental role of soil organisms in agroecosystems, investigations on their interactions with pesticides should receive more attention.

MO258

Sublethal effects of epoxiconazole on the earthworm Aporrectodea icterica

N. CHEVIRON, INRA/AgroParisTech / UMR ECOSYS Plateforme BiochemEnv; c. pelosi, INRA Institut National de la Recherche Agronomique / UMR ECOSYS Platform BiochemEnv; L. Beaumelle, IRSN/PRP-ENV/SERIS/LRTE; G. Delarue, S. Nélieu, INRA Institut National de la Recherche Agronomique / UMR ECOSYS

Earthworms play a key role in agroecosystem soil processes. This study aims to assess the effects of different doses of a commercial formulation of epoxiconazole (Opus®), a persistent and widely used fungicide, on the earthworm *Aporrectodea icterica*. A laboratory study was conducted in a natural soil in order to measure effects of Opus® on earthworm mortality, uptake, weight gain, enzymatic activities (catalase and glutathione-S-transferase), and energy resources (lipids and glycogens). The estimated LC50 was 45.5 mg kg^{-1}, or 268 times the recommended dose. Weight gains were 28, 19, and 13 % of the initial weight after 28 days of exposure in the control and D1 and D10 (1 and 10 times the recommended dose) treatments, respectively. No difference was observed for catalase activity between the three treatments, at 7, 14, or 28 days. The glutathion-S-transferase (GST) activity was two times as high in D1 as inD0 at 14 days. At 28 days, glycogen concentration was lower in D10 than in the D1 treatment. This study highlighted moderate sublethal effects of the commercial formulation Opus® for earthworms. Considering that these effects were observed on a species found in cultivated fields, even at recommended rates, much more attention should be paid to this pesticide. **Keywords:** Ecotoxicology, Fungicide, Biochemical biomarkers, Mortality

MO259

Poplar-assisted bioremediation of a PCB historically contaminated soil in Southern Italy

V. Ancona, National Research Council / Water Research Institute; P. Grenni, National Research Council of Italy (CNR) / Water Research Institute; A. Barra Caracciolo, National Research Council of Italy / Water Research Institute; D. Martina, Natonal Research Council / Water Research Institute; C. Campanale, A. Calabrese, V. Uricchio, National Research Council / Water Research Institute; G. Mascolo, National Research Council; A. Massacci, National Research Council / IBAF

The plantation of selected plants in contaminated sites can support organic contaminant degradation. Plant roots can release exudates and supply nutrients useful for autochthonous microorganisms, which in turn enhance their biological activities and can degrade xenobiotics. A synergistic action between rhizosphere microorganisms and plants can lead to an increase in bioavailability of hydrophobic compounds, making them more susceptible to degradation. The results of the first 30 months of a poplar-assisted bioremediation application to a multi-contaminated (PCBs and heavy metals) soil in Southern Italy are here reported. The investigated site has been used for several decades as an unsupervised waste disposal. A specific poplar clone (Monviso), was applied in an area of 785 m^2 of the contaminated site where six hundred poplar cuttings were planted. Sampling were performed 14 and 30 months after the poplar-plantation. At each sampling, soils at different depths and distance from the tree trunk, tree roots and leaves were collected for chemical and microbiological analysis. PCB and heavy metal (HMs) analyses were performed using a GC-MS and an ICP-MS, respectively. Microbial analysis were carried out to assess total microbial abundance, cell viability and dehydrogenase activity (DHA) of the autochthonous microbial community. The comparison of the chemical and microbiological analyses performed at day 0 and 14 and 30 months after the poplar plantation, show a decrease in soil of PCBs under the Italian legislation limits and also a significant decrease in soil of all HMs. The poplar plantation showed its effectiveness both in promoting the persistent organic contaminant degradation and in the phyto-containment of the inorganic ones. In line with these results microbiological activity increased significantly in the rhizosphere soil.

MO260

Re-calibration of the earthworm tier 1 risk assessment of plant protection products

M. Coulson, Syngenta; H. Christl, Tier3 Solutions GmbH; J. Bendall, Dow Agrosciences; A. Dinter, DuPont de Nemours (Deutschland) GmbH / Crop Protection; B. Garlej; P. Kabouw, BASF SE; A. Sharples, Cheminova A/S; G. von Mérey, Monsanto Europe S.A. / Regulatory; G. Ernst, Bayer CropScience AG / Ecotoxicology

To address potential risks of plant protection products to earthworms, a risk assessment is required. This risk assessment comprises two steps 1) deriving no-observed effect levels (NOEL) from laboratory reproduction tests and applying a trigger value, to cover uncertainties, and if this indicates a potential risk, 2) conducting field studies. In this review paper the tier 1 earthworm risk assessment for plant protection products is calibrated by comparing the NOEL in laboratory earthworm reproduction tests with effect levels on earthworm populations under realistic field conditions. A dataset of 54 pairs of studies conducted in the laboratory and in the field with the same plant protection product was compiled, allowing a direct comparison of relevant endpoints. The results indicate that a tier 1 assessment factor (AF) of 5 combined with a regulatory relevant soil layer of 0-5 cm provides a conservative tier 1 risk assessment. A risk was identified by the tier 1 risk assessment in the majority of the cases at application rates which were of low risk for natural earthworm populations under field conditions. Increasing the conservatism in the tier 1 risk assessment by reducing the depth of the regulatory relevant soil layer or by increasing the tier 1 AF would increase the number of false positives and trigger a large number of additional field studies. This would however not increase the margin of safety for earthworm populations. The analysis revealed that the risk assessment is conservative if an AF of 5 and a regulatory relevant soil layer of 0-5 cm are used.

MO261

Determination of Soil Adsorption Coefficient (Koc) Values for a Series of Aliphatic Alcohols using the OECD 121 HPLC Method

C.V. Eadsforth, Shell International / Shell Health; J. Dawick, Shell International / Shell Health Risk Science Team; T. Corry, Shell Global Solutions / Analysis and Measurement; R.J. Wildey, O. Dosunmu, Peter Fisk Associates; P.R. Fisk, Saxon House

A study has been performed to generate experimental data for the organic carbon-water adsorption coefficient (Koc) of a range of alcohols (C6-C16) using an accepted OECD method (OECD 121). This Test Guideline describes an experimental method using High Performance Liquid Chromatography for the estimation of the adsorption coefficient Koc. The HPLC method is an estimation method based on correlation of retention data with true Koc values determined in soil/sediment/sludge-water systems. A series of reference substances, as recommended in the OECD 121 guideline, were assessed using a HPLC system under the specific conditions outlined in the method. The retention data were used to generate a correlation plot of literature adsorption coefficient (log Koc) values and the log capacity factor (k) for the reference substances. A range of linear alcohols, ranging from C6 (1-hexanol) to C16 (1-hexadecanol), was subsequently run under the same HPLC conditions and their capacity factors (k) generated. The calibration line (log k vs log Koc) for the reference substances was then used to generate the estimated log Koc values for all the individual linear alcohols. Applying the OECD 121 guideline method, the HPLC-derived log Koc values for these alcohols ranged from 1.25 (1-hexanol) to 5.40 (1-hexadecanol). When taking into account other experimental log Koc data from sewage sludge adsorption studies (n = 4) and a recent OECD Guideline 106 test for 1-decanol, very good agreement with HPLC screening data was obtained. The HPLC log Koc value for 1-decanol was within a factor of 2 compared to the value obtained from the OECD 106 study which demonstrates the accuracy of the technique. However, QSAR predictions of log Koc vary widely in comparison to HPLC and measured data depending on which QSAR method (regression-based log Kow or fragment-based Molecular Connectivity Index) is selected. This study demonstrates the good performance of the HPLC screening method for determination of log Koc of aliphatic alcohols without the complications associated with definitive experimental determination using the OECD 106 method due to their rapid biodegradability. An evaluation of the various QSAR based methods for prediction of log Koc for aliphatic alcohols is also discussed.

MO262

How representative is Eisenia andrei as a standard species for soil ecotoxicological testing?

S. Reinecke, Stellenbosch University / Dept Botany and Zoology; A. Reinecke, Stellenbosch University / Botany and Zoology

The widely distributed composting earthworm species *Eisenia andrei* is recommended and used for ecotoxicological testing. However, the scientific literature abounds with scepticism about its suitability and its representativeness because it is a litter-dwelling species representing a totally different ecotype than most other soil dwelling oligochaetes. To address the question whether toxicity data obtained with *E. andrei* could be extrapolated on reasonable grounds to other earthworm species, we compared the sensitivity of *E. andrei* and four other species representing different ecotypes. *E. andrei, Aporrectodea trapezoides, Amynthas diffringens, Perionyx excavatus* and an indigenous *Chilota* species were exposed under similar conditions to a concentration series of copperoxychloride as prescribed by OECD guidelines for toxicity testing. We monitored mass change and cocoon production over time and compared body copper accumulation at the end of the exposure. No worms in the uncontaminated control soil or in the 20mg/kg exposure lost significant body mass. With exception of *A. trapezoides* no other species lost significant mass at 80 and 160 mg/kg exposures. At 320 mg/kg exposure significant differences occurred between species with *E. andrei* and *P. excavatus* (the two litter-dwelling species) seemingly more robust. Cocoon production differed between the composting and soil dwelling species with the latter two species being more severely affected. Body concentrations of Cu increased similarly with increasing exposure concentrations in all species. At the lower, environmentally more relevant concentrations mass change and body load of Cu were not strong discriminating factors. However at the higher concentrations it clearly affected the soil dwelling species more detrimentally. Cocoon production was a more sensitive endpoint than body mass change and a distinction between the soil dwelling and the litter dwelling species was obvious at lower concentrations. The simultaneous onset of the detrimental effect of copperoxychloride on cocoon production (albeit at different levels of severity) in all species provided evidence that extrapolation to other species may be warranted, provided that the results are interpreted with the necessary caveat that the intensity of effects may differ as a result of differences in habitat type and lifestyle.

MO263

Monitoring the residues of currently used pesticides in agricultural soils - the first step of the post-registration control

J. Hofman, Masaryk University, RECETOX / Faculty of Science RECETOX; M. Hvezdova, Masaryk University / Faculty of Science RECETOX; P. Kosubova, Central Institute for Supervising and Testing in Agriculture; Z. Simek, Masaryk University / Research centre for toxic compounds in the environment; M. Sanka, Masaryk University / Central Institute for Supervising and Testing in Agriculture; J. Vasickova, Masaryk University / Faculty of Science RECETOX; L. Bielska, RECETOX, Faculty of Science, Masaryk University / Faculty of Science RECETOX; M. Sudoma, M. Svobodova, L. Skulcova, Masaryk University / Faculty of Science RECETOX

Data on currently used pesticides (CUPs) in surface and ground water are relatively abundant due to ongoing water monitoring in many EU countries. Several CUPs or/and their degradation products have been repeatedly found at high frequency and also at considerable concentrations. Water monitoring scientists have hypothesized that the secondary source of CUPs in water are soils in watershed that keep the residues for long time and slowly release them (or their degradation products) to ground/surface water. However, there are surprisingly no data available for CUPs in soils in EU to work on this hypothesis. Not only for the purpose above, but also for the post-registration control of approved plant protection products, the monitoring of CUPs in Czech agricultural soils was performed last year. Fluvisols (alluvial soils) were selected for the study as they are intensively used for agriculture and actively communicating with surface/ground water. Soil samples were collected in February to March to address the "long-term" ("oldest possible") residues before new pre-emerging applications and to avoid the peaks caused by recent applications. In 75 soils, 65 active ingredients were determined by multiple residue method using QuEChERS extraction and UPLC-MS/MS detection. The results identified several CUPs frequently found above LOQ. The most frequently detected compounds were azole fungicides epoxiconazole (36% of samples), tebuconazole (27%), flusilazole (17%), prochloraz (16%), and propiconazole (10%). Their mean concentrations in positive samples were about 0.01 mg/kg. The second most frequently detected compound was 2-hydroxy atrazine (29%) with mean concentration in positive samples about 0.03 mg/kg and the highest measured concentration of 0.135 mg/kg. This finding is surprising as atrazine was banned in CR in 2006. It can also explain still frequent detections of atrazine degradation products in water monitoring. Other CUPs with frequent findings were fenpropidin (15%), diflufenican (13%), terbuthylazine (13%) and others. The results also show how complex is the mixture of CUPs in current agricultural soils - half of the soils had 5 or more CUPs detected. The soil residues of CUPs should be definitely considered and soil monitoring programs for CUPs should be initiated in EU countries along with water monitoring. Financial support was obtained from GACR project 15-20065S.

MO264

PERSAM PECsoil calculation and pesticides risk assessment: support or burden for regulators?

S. Ullucci, L. Menaballi, M. Luini, International Centre for Pesticides and Health Risk Prevention; F. Marchetto, ICPS; A. Riva, C. Riva, F. Galimberti, International Centre for Pesticides and Health Risk Prevention; A. Moretto, Università degli Studi di Milano

Pesticide risk assessment for soil organisms is currently performed by calculating the toxicity/exposure ratio, that is the comparison of the toxicity that a specific pesticide has for a soil not-target organism and the pesticide exposure predicted for that same organism. The substance toxicity is assessed with targeted ecotoxicological studies on certain representative species, while exposure is assessed by calculating a Predicted Environmental Concentration (PEC) with models. According to the new EFSA Guidance Document for predicting environmental concentrations of active substances of plant protection products and transformation products of these active substances in soil (EFSA Journal 2015;13(4):4093) the new model PERSAM has to be used for the calculation of pesticides PEC_{soil}. This model is structured in five Tiers with different levels of complexity. Tier 1 is a very conservative one while the higher Tiers, even if closer to realistic conditions, are quite complex and time-consuming since the entire calculation process is quite slow and long-lasting. This work addresses such a complex exposure assessment in the context of the standard evaluation procedure that regulators have to deal with in their activity of registration of both active substances and PPPs. In particular, attention will be focused on how often a higher tier results necessary and how often Tier 1 may be used to exclude pesticide of low risk for soil non-target organisms. A subset of Plant Protection Products (insecticides and fungicides, the substances that generally may pose some risk to soil non-target organisms) authorized at National level has been considered. Ecotoxicological endpoints on soil arthropods and earthworms (NOEC and EC_{50}) have been taken mostly from EFSA Conclusions and Review Reports and recorded in an MS Excel spreadsheet. RAC (Regulatory Acceptable Concentrations) have been derived from these endpoints. PEC_{soil} for the selected active substances have been calculated with PERSAM and with the simple tier 1 presently used in registration and then compared with the RAC. The percentage of active substances which showed an unacceptable risk for each Tier has been calculated, and comparison between the old system and the new one has been presented together with some considerations on the efficacy, reliability and usefulness of all the PERSAM tiers.

MO265

From bioavailability science to regulation of organic chemicals: a communication experiment

J. Ortega-Calvo, Instituto de Recursos Naturales y Agrobiologia / Agroquimica y Conservacion del Suelo; J. Harmsen, Alterra, Wageningen-UR / CALM; J. Parsons, University of Amsterdam / IBED; J. Roembke, ECT Oekotoxikologie GmbH; K.T. Semple, Lancaster University / Lancaster Environment Centre

The bioavailability of organic chemicals (i.e., mainly industrial chemicals, pesticides, biocides and pharmaceuticals) in soil and sediment is an important area of scientific research. However, this area remains only partially recognized by regulators and industries working in the environmental sector. Based on the positive experiences already made with metals, regulators have recently started to consider bioavailability within retrospective risk assessment (RA) frameworks (e.g. of contaminated sites) for organic chemicals. By doing so, realistic decision-making in terms of hazard definition and priority considerations finally resulting in optimised cost allocation can be achieved, rather than relying on the established approach of using total-extractable concentrations. However, implementation of bioavailability remains difficult because scientific developments on bioavailability are not always translated into ready-to-use approaches for regulators and, therefore, no integrated approach for implementation is available. For the same reason, bioavailability remains largely unexplored within prospective regulatory frameworks (e.g. REACH) that address the approval and regulation of organic chemicals. To facilitate the inclusion of bioavailability within more realistic RA frameworks, agreement and common understanding between scientists and regulators is required. This contribution has been prepared by the five proposing authors that represent a bigger group of authors from academia, industry and regulation, who have recently arrived at an agreement and discussed bioavailability concepts and methods. In addition, we offer a simple, pragmatic and justifiable approach for use within retrospective and prospective risk assessment. A key motivation for this communication exercise was the differences between scientific and regulatory perception. The developments achieved at the Special Science Symposium focused on bioavailability, organized in 2014 by SETAC Europe (http://sesss10.setac.eu/), subsequently led to a featured paper (Environ. Sci. Technol. 49:10255-10264, 2015). In the paper, we propose a simplified approach in which the assessments of soil/sediment and the target chemicals should be based on two measurable values: the total extractable concentration, and the bioavailable concentration as measured with robust and reproducible chemical and/or biological methods (desorption extraction, passive sampling, aqueous extraction, and/or biological tests).

MO266

General overview of experimental terrestrial toxicity studies submitted in the framework of the REACH Regulation

A. Rodriguez Ruiz, European Chemicals Agency - ECHA / Zoology   Animal Cell Biology; M. Sobanska, European Chemical Agency - ECHA; D. Jevtic, Institute of Environmental Sciences, Jagiellonian Univeristy / Ecotoxicology and Stress Ecology; R. Cesnaitis, European Chemicals Agency; F. Gissi, CSIRO Oceans and Atmosphere / CSIRO Oceans and Atmosphere; T. SOBANSKI, European Chemical Agency; A. Kapanen, European Chemicals Agency - ECHA

The REACH Regulation entered into force in June 2007. Since then European Chemicals Agency (ECHA) has received a large amount of scientific and administrative information related to chemical substances submitted in the registration dossiers. To avoid unnecessary testing, the REACH Regulation provides registrants with the possibility to build testing strategies and to adapt the standard information requirements based on the specific conditions listed in the Regulation. In order to understand what type of data on terrestrial ecotoxicity were submitted in REACH registration dossiers, a detailed analysis of the availability and content of relevant information was performed. The similar analysis was performed after the first registration deadline (Versonnen et al., 2013). The current analysis covers the data submitted for the two registration deadlines (1 December 2010 and 1 June 2013) and new experimental data produced as a consequence of the evaluation of testing proposals and the compliance checks. As in the previous analysis, both the most used test guidelines and test species were investigated. As the outcome of the conducted analysis, it can be concluded that for soil invertebrate testing mostly standard guidelines were used and consequently, a clear prevalence has been detected for testing on the species recommended by the standard test guidelines. Nevertheless, the reporting included a large variety of species from very different families. For terrestrial plants, the most extensively reported test guidelines were OECD 208, ISO 11269-1 and ISO 11269-1. It is important to stress that for many cases, the information on the test guideline according to which the study was conducted, was not reported or was not reported correctly. Moreover various adaptations and waiving justifications were used to omit the experimental testing for terrestrial toxicity. When interpreting the findings of the current analysis, it should be noted that in principle the current results may be affected by the outcome of the dossier evaluation works performed by ECHA. By November 2015, ECHA had issued more than 100 final decisions, which requested terrestrial toxicity studies to be performed according to standard test guidelines. The analysis of the terrestrial ecotoxicity data submitted by registrants to fulfil REACH data requirements will be presented.

MO267

Natural transformation of chlordecone into 5b-hydrochlordecone in French West Indies soils: statistical evidence for investigating long-term persistence of organic pollutants

D.A. Devault, Université Paris Sud / Ecologie Systématique et Evolution; C. Laplanche, Ecole Nationale Supérieure Agronomique de Toulouse (ENSAT) / Ecolab Laboratoire décologie fonctionnelle et environnement; S. Bristeau, BRGM / Division Laboratoires; C. Mouvet, BRGM; H. Macarie, IRD / IMBE UMR IRD

Chlordecone (CLD) was an organochlorine insecticide whose previous use resulted in an extensive pollution of the environment with severe health effects and social consequences. A closely related compound, 5b-hydrochlordecone (5b-hydroCLD), has been searched for and often detected in environmental matrices from the geographical area where CLD was applied. The current consensus considered that its presence was not the result of a biotic or abiotic dechlorination of CLD in these matrices but rather the consequence of its presence as impurity (synthesis by-product) in the CLD released into the environment. The aim of the present study was to determine if and to what extent degradation of CLD into 5b-hydroCLD occurred in the field. To test this hypothesis, the ratios of 5b-hydroCLD and CLD concentrations in a dataset of 810 soils collected between 2006 and 2012 in Martinique were compared to the ratios measured in representative samples of commercial formulations. The statistical analysis highlights the unexplained high amount of 5b-hydroCLD in soil associated with the CLD spread. The hypothesis proposed for explaining why 5b-hydroCLD/CLD ratios in soils exceed the corresponding ratio in commercial formulation leads to the inverse demonstration: 5b-hydroCLD should be preferentially eluted from soil by water and may be metabolized, strengthening the significance of the statistical evidence demonstrating that 5bhydroCLD amounts in field soil cannot be justified by its sole input as an impurity present in the Kepone® and Curlone® commercial formulations. The bishomocubane structure of the compounds invalidates all the other origins unless CLD. Results showed a significant increase of the 5b-hydroCLD/CLD ratio in the soils—25 times greater in soil than in commercial formulations— when the investigations dealing with the differential transfer of 5b-hydroCLD compared to CLD lead to promote a decreasing mass ratio in situ compared to the formulation, the opposite of the trend observed. This suggested that natural CLD transformation into 5b-hydroCLD over the long term occurred in these soils. Previously, considered as a by-product due to CLD synthesis, 5b-hydroCLD turns to be a highly probable dechlorination product of CLD. However, the details on 5b-hydroCLD formation are still to be determined although some potential pathways for this formation could be advanced. Results from this study may impact future decisions for the remediation of the polluted areas.

MO268

Toxicity depends on the life stage: proposal for a new testing method using Folsomia candida

B.M. Guimarães, Universidade de Aveiro/CESAM; J. Roembke, ECT Oekotoxikologie GmbH; M.J. Amorim, Universidade de Aveiro / Department of Biology and CESAM

Toxicity of pollutants depends on the life stage of the test organisms. Different sensitivities between juveniles and adults on earthworms have been reported, meaning that often juveniles are more sensitive than older stages. Current test methods seldomly cover this aspect and may underestimate toxicity. Hence the development of new test methods to assess the environmental risk of contaminants is of high interest. The aim of this study was to develop and assess a novel test method using the standard test species *Folsomia candida*. The current OECD test is standardised for the exposure of juvenile organisms being 10-12 days old. In the present study the toxicity of Cd was compared between 3 different developmental stages: eggs, juveniles (10-12 days) and adults (21 and 28 days old). Results showed that Cd was not affecting significantly the hatching success of *F. candida* at 60mg/kg (the reproduction EC50), but survival of juveniles was affected as well as reproduction. These effects were stronger compared to the results of 10-12 days old organisms. Exposure of adults to Cd showed less effect in terms of reproduction compared to those effects observed after exposure of juveniles. The present assessment of effects at different life stages allows to identify the stageat which the effects occurred. Moreover, exposure of eggs enhanced the effects in terms of reproduction compared to exposure of juveniles and adults.

MO269

Effects assessment on terrestrial organisms: Integrated testing strategy under the REACH Regulation

R. Cesnaitis, European Chemicals Agency; M. Sobanska, European Chemical Agency - ECHA; V. Bonnomet, European Chemicals Agency   ECHA; D. Jevtic, Institute of Environmental Sciences, Jagiellonian Univeristy / Ecotoxicology and Stress Ecology; A. Rodriguez Ruiz, European Chemicals Agency - ECHA / Zoology   Animal Cell Biology; A. Kapanen, European Chemicals Agency - ECHA

The scope of the terrestrial effect assessment under REACH is restricted to soil non-vertebrate organisms living the majority of their lifetime in the soil and being exposed to substances through the soil pathway. Under REACH framework risks to predators from the secondary poisoning due to chronic exposure to a substance through the terrestrial food chain should also be assessed by registrants. The REACH “standard information requirements” are listed in Annexes VII to X to the REACH Regulation. The minimum dataset depends on the annual tonnage (tpa), i.e. quantity manufactured or imported by a registrant per year. This principle also applies to the standard terrestrial toxicity data necessary to be provided in the REACH registration dossier. For registrations from 100-1000 tpa, results of short-term toxicity studies on soil invertebrates and plants should be provided together with the results of toxicity study for soil microorganisms. When the registration tonnage is above 1000 tpa, long-term toxicity studies with soil invertebrates and plants should be provided. For highly adsorptive (log Kow >5) and very persistent substances (half-life in soil >180 days), long-term toxicity data instead of short-term data should be considered even at registration tonnage from 100-1000 tpa. Column 2 of REACH Annexes IX and X lists specific rules for adaptation of the “standard information requirements”. In case of terrestrial toxicity data, the studies do not need to be conducted if direct and indirect exposure of the soil compartment is unlikely. Besides, the equilibrium partitioning method (EPM) may be applied to assess the hazard to soil organisms. The principles and practicalities of soil hazard assessment are summarised in ECHA's *Chapter R7c Guidance*. It provides the integrated testing strategy for assessment of effects on terrestrial organisms. ECHA in co-operation with other REACH stakeholders has processed a number of dossier evaluations where various issues of terrestrial effect assessment were addressed. Based on these discussions, the screening assessment approach for soil, the criteria to define substances with high potential for adsorption and substances very toxic to aquatic organisms were further clarified. Moreover, the threshold given in some standard soil toxicity test guidelines was questioned and respective analysis to identify new relevant parameter(s) and threshold(s) to define volatile substances for the purpose of soil toxicity testing was performed.

Risk Assessment of Biocides - latest developments (P)

MO270

Example of a conceptual garden scenario and potential for ecosystem services and ecological modelling to support the regulatory process

F. Ericher, CEA; S. Taylor, Cambridge Environmental Assessments

At the present time, outdoor risk assessments of biocidal consumer products are typically based on the impact they have on the immediate treated area. Recovery at the scale of the garden, rather than the treated soil, is not generally considered when reviewing the risk and benefit of the product. This poster aims to demonstrate how treated area and the garden itself could be considered as a part of a larger urban environment, where the fraction of impacted soil can be balanced with the potential for recovery. In addition, consideration should be given to the role of the product and the ecological relevance of the treated area with respect to the urban environment. Finally, the importance of a consensus on the ecological relevance of urban area is highlighted, in order to provide effective guidance to risk assessors.

MO271

Aspects of scoping and running environmental risk assessment for a Biocidal Product Family

C. Durou, CEHTRA SARL; A. Barret, E. Beltran, L. Pontal, R. SAMSERA, CEHTRA SAS; S. Kirkham, CEHTRA UK ltd

The Biocidal regulation requires an environmental risk assessment (ERA) to be performed on the active substance (AS), for the precursor(s) of in-situ generated AS and for any substance of concern (SoC) present in any biocidal product (BP) to be marketed on the EU market. In the meantime, the regulation allows the creation a biocidal product family (BPF) in order the to facilitate a group of products to access the market. Within a BPF, all BP have the same AS and have similar uses. Variations in the composition, replacement of non-active substances is allowed, providing that change do not affect the level of risk or reduce the efficacy. The number of BP and AS in a BPF is not defined. A simple and straightforward BPF includes a single AS and omits any SoC. However, more complex BPF may be built and include more than one AS and SoC for environment. Since the assessment of the BPF shall consider the maximum risks to the environment over the whole potential range of products within the BPF, preliminary risk assessments is needed to define the scope of ERA (i.e. compartment at risks, composition leading to maximum risks). The initial step is to gather all necessary information for running preliminary risk assessment: -Product Type, detailed information on use claimed -Identification of relevant emission scenario document. However, for many biocide uses, no ESD have been developed and will require tailor-made scenarios to be performed -Quantitative composition and variation of components within the BPF -Collecting hazard data for all components including PNEC values Which methodology to be applied for running the risk assessment? Various methods have been proposed to assess the risk of mixture for the environment. This includes e.g. component-based approach. Among the modelling tools, EUSES has been extensively used for the assessment of risks posed by AS under the review program of existing AS. The methodology is quite clear for assessment of BPF containing a single AS, the picture much more complicated with combination of AS and SoC. A transitional guidance has been made available by ECHA. This poster will address a hypothetical case study with BPF containing more than one AS and relevant substance to assess together with a combination of wide dispersive use. The purpose of this work is to initially review the issues with ERA for BPF, the need for an adaptable methodology able to cover complexities associated with variation of composition and uses.

MO272

Replacement possible for biocides with carcinogenic formaldehyde

J. Wezenbeek, M. Janssen, J. Scheepmaker, RIVM / Centre for Safety of Substances and Products

The National Institute of Public Health and Environment (RIVM) made an inventory of the use of formaldehyde in disinfectants and preservatives (biocides) and the availability of alternatives. There seem to be sufficient alternatives available for the majority of disinfectants and preservatives containing the carcinogenic substance formaldehyde. However, the suitability of these alternatives needs to be reviewed per sector and application. Formaldehyde is the active substance in many disinfectants and preservatives. It is expected to be classified as carcinogenic by 1 January 2016 at European level. This can have implications for the use of biocides containing formaldehyde that are currently on the market. In the Netherlands, the disinfectants and preservatives that are made available on the market are assessed by the Board for the Authorisation of Plant Protection Products and Biocides (Ctgb) and authorised as safe when used according to the product label. These products are used by professionals only. There are alternatives for the following applications: cleaning and disinfection of surfaces and instruments in the healthcare sector; disinfection of indoor public areas; disinfection of stables and animal housing; preservation of detergents and cleaning products; preservation of paints, varnishes, inks and other industrial liquids, preservation of liquids in cooling systems and for slime control in the paper and pulp industry. For some applications, very few alternatives were found. This lack concerns, for example, the disinfection of mushroom-growing rooms, litter bins for sanitary towels, footwear and cattle hooves. This also applies to some preservation products, such as in lubricants, metalworking fluids, and the preservation of human and animal corpses and biological tissues. The Dutch Ministry of Infrastructure and the Environment will use the inventory to review – in collaboration with industry branches – whether there will be bottlenecks when the use of formaldehyde is further restricted. Also, the study will be used to inform users about the need to restrict exposure to formaldehyde and formaldehyde emissions as much as possible. This is in line with the current policy of the Ministry of Infrastructure and the Environment for priority substances of concern (ZZS substances). The Ministry aims to substitute the use of formaldehyde with less hazardous substances and to stimulate the use of non-chemical alternatives.

MO273

Harmonizing the environmental risk assessment for antifouling paints

J. Wezenbeek, E. Smit, RIVM / Centre for Safety of Substances and Products

Active substances (biocides) to be used in antifouling paints are authorized on a European level using a harmonized risk assessment method. An active substance can be authorized in Europe if the use on commercial sea ships does not lead to unacceptable effects on the ecosystem immediately outside a commercial seaport. After an active substance is authorized, industry has to apply for national authorization of the formulated antifouling paints to bring such products on the market. There is an obligation of mutually acceptance of authorizations between European member states, but the product authorization methods are not yet harmonized. Some countries have no authorization method at all, and where methods exist, they differ in several aspects. The absence of a harmonized approach hampers the free movement of goods and may eventually lead to a shortage of suitable products. In this respect, it should be noted that antifouling paints also provide social and environmental benefits, by reducing fuel consumption and preventing the spreading of invasive species. Besides ship yards will suffer economic damage when companies move outside the European Union because effective antifouling paints can no longer be applied here. To solve this problem, the Netherlands initiated the process in which European member states and stakeholders will work to develop a harmonized approach for national authorizations. Agreement is needed on which type of ships and harbors should be included (commercial or pleasure crafts), which part of the aquatic environment is to be protected (only marine waters or also freshwaters, outside or also inside harbors), and how to include the risks of application, maintenance and repair in the risk assessment. A further step is to develop exposure models that are harmonized with respect to e.g. dimensions and hydrology of the harbor and surroundings, the number and size of ships at berth and moving, and the fraction of ships treated with antifouling paint. In addition, the methodology should account for the fact that environmental characteristics (salinity, temperature, pH, DOC, etc.) differ between countries. Other issues are how to account for market share, and how to deal with mixtures of active substances. In the end, the harmonized approach should deliver estimates of exposure that represent a 'realistic worst case' for different countries or regions. The first results will be presented at the conference.

MO274

Testing antifouling sealers efficiency and toxicity

J. Ferreira, Environmental Science and Analytical Chemistry ACES; B. Eklund, Stockholm University / Department of Environmental Science and Analytical Chemistry; M. Lagerström, M. Bighiu, A. Eriksson-Wiklund, Stockholm University / Environmental Science and Analytical Chemistry ACES

Application of antifouling paints (AP) is the method most commonly used to prevent the development of marine biofouling on boat surfaces. Leakage of toxic agents from AP on boat hulls is one of the main sources of biocide release into water bodies. The scale of the problem is easily appreciated taking into account that 6 million boats move within Europe and components of AP, such as copper, zinc, irgarol and TBT, can be highly toxic to the environment. Application of multiple layers of AP onto boat hulls over the years is a common practice among boat owners, which has lead to the maintenance of banned paint components, such as TBT, on boat hulls. The application of new layers of AP on boat hulls is normally preceded by the use of sealer coats (SC), which are developed to prevent product incompatibilities and leaching from older paint layers. Therefore, the efficiency of such SC is of importance if leaching from older paint products to the environment is to be avoided, especially nowadays with the increase usage of mechanical brushing devices for removal of biofouling from boat hulls. In this study, manipulative laboratory based experiments tested the performance of five SC from leading paint producers. Sealer coats efficiency in locking underlying AP, its resistance to brushing action and toxicity to aquatic organisms were evaluated. The toxicity of SC leachates produced in 7‰ natural seawater was tested on four organisms, the bacterium *Vibrio ficheri*, the alga *Ceramium tenuicorne*, the crustacean *Nitocra spinipes* and the gastropod *Theodoxus fluviatilis*. All SC showed to be toxic, causing increased mortality, inhibition of growth or bioluminescence inhibition, to at least one of the tested species. In terms of locking efficiency, none of the SC showed to be able to successfully lock biocide release from all the AP tested. Locking capacity of SC was dependent on the underlying layer of AP being tested and identity of the metal being released, with brushing action generally reducing locking efficiency of SC. Our results emphasise the need to improve the locking efficiency of SC in order to prevent release from underlying AP. Moreover, we showed that the use of mechanical brushing devices on SC is also not recommended as it reduces SC locking capacity and consequently increases leaching rates from underlying paints. As SC leachates were toxic to tested organisms, the use of biological tests in the regulatory process of such products is recommended.

MO275

Emissions and photo-transformation of biocides on building facades using the example of terbutryn

U. Bollmann, Aarhus University / Environmental Science; G. Minelgaite, Aalborg University / Civil Engineering; M. Schluesener, German Federal Institute of Hydrology; T. Ternes, German Federal Institute of Hydrology BfG; J. Vollertsen, Aalborg University / Department of Civil Engineering; K. Bester, Aarhus University / Environmental Science

Biocides as triazines or isothiazolinones are added to render and paint in order to protect building facades from microbial deterioration. Previous studies have shown that biocides leach out of the material during rain events and can be detected in the urban environment. In the present study the leaching of terbutryn from artificial walls equipped with two types of render (acrylate and silicone resin render) was observed for 19 months. On the one hand, the emissions of terbutryn (concentration and mass load) were determined; on the other hand, photodegradation products were identified and studied in the leachate as well as the render. It could be shown that biocides leach predominantly within the first months of the facade lifetime. While the leaching was determined by driving rain within this period the leaching was reduced afterwards and determined by other factors. Several photo-transformation products could be detected in the façade runoff. However the major fraction of the transformation products was still remaining in the façade material. Based on the amount of terbutryn and its transformation products in the leachate as well as remaining in the material, the overall mass balance can be closed. This study showed, that the focus on transformation products during the assessment of biocides in building material is of high importance: not only concering the emissions during life-time, but also when it comes to disposure of the coating material as waste.

MO276

Non-monotonic dose-response relationships for toxicity of the biopesticide DiPel ES on Daphnia magna

A. de Souza Machado, Leibniz Institute of Freshwater Ecology and Inland Fisheries / Ecophysiology and Aquaculture; C. Zarfl, University of Tuebingen / Center for Applied Geosciences; S. Rehse, Leibniz-Institute of Freshwater Ecology and Inland Fisheries / Ecophysiology and Aquaculture; W. Kloas, Liebniz Inst. of Freshwater Ecology & Inland Fish.

Currently, there is a trend to increase the use of supposed environmentally friendly biopesticides. In this context, *Bacillus thuringiensis* (BT) pesticides, such as DiPel ES, are amongst the worldwide most used to control caterpillars. BT produces endotoxins that cause effects described as highly specific to some insects. These biopesticides are used worldwide without environmental limits because they are considered to present negligible toxicity to non-target organisms. This study investigated the toxic responses of the non-target organism *Daphnia magna* to waterborne DiPel ES. Neonates were 48h-exposed to DiPel ES for LC50 and EC50 estimation. *D. magna* 17-21 days old were similarly exposed for EC50 and biomarkers. The biomarkers evaluated (whole body) were body weight, global protein, chitobiase, catalase, glutathione reductase, glutathione S-transferase, and acetylcholinesterase. Particle size distribution in the exposure media was determined by preliminary measurements.Dipel affected immobilisation and mortality of neonates ($p>0.001$, EC50=from 0.17 to 0.20μL/L, LC50=0.40 to 1.17μL/L). Similar sensibility was found for immobilisation of adult daphnids (EC50= from 0.17 to 0.29μL/L), without significant mortality. Mortality and immobilization endpoints displayed a biphasic and inverse U-shaped response. All biomarkers but acetylcholinesterase were affected by DiPel ES exposure ($p< 0.05$), displaying multiphasic dose-responses. This suggests a mechanism of toxicity able to affect generally organs and systems of the whole organism. The main particle size in experimental media was compatible to bacteria spore, however a secondary particle size compatible to metabolic active BT, was observed when toxicity was occurring. Therefore, it is possible that chemical and physiological interactions resultant of different BT activity at various DiPel ES concentrations might be related to the observed non-monotonic effects. The core assumption of current toxicology is that toxicity increases monotonically with contaminant exposure. However, the present results challenge the universal applicability of this central ecotoxicological principle. Further studies are required to isolate the cause of non-monotonicity of this BT biopesticide.

MO277

Secondary poisoning risk assessment for insectivorous species under Biocidal Products Regulation: case of insecticides used against ants

V. Larno, A. Scelo, ANSES

The risk of secondary poisoning is a part of the environmental risk that has to be assessed under the Biocidal Products Regulation 528/2012. It relates to toxic effects occurring in higher levels of food chains which result from ingestion of contaminated organisms from lower trophic levels. Insectivorous animals have potentially a risk of secondary poisoning through eating treated insects, especially during the outdoor use of insecticidal products, like those against ants. A harmonized approach to assess the secondary poisoning risk for insectivorous birds or mammals is actually available in the Exposure Scenario Document for household and professional insecticides (ENV/JM/MONO(2008)14). However, this approach based on the SANCO/4145 (2002) EU guidance for Plant Protection Products is relevant only for spray products and not for other type of application such as gel bait often used against ants. This poster describes an example of biocidal use for which an exposure scenario is currently not available. It presents first reflections on the parameters which could be considered for the construction of a new model of exposure more specific to gel bait product against ants. Considerations related to the type of product, its mode of action, specificities of target (here ants) and predator species (behavior, biology) are exposed and discussed for a future scenario that could better reflect the realistic worst case of secondary contamination of insectivorous species eating ants treated with a gel. Due to the variety of uses, target organisms and application types, the biocidal environmental risk assessment regularly requires the adaptation or development of new exposure scenarios which complete existing European guidance documents and enhance the environmental risk assessment.

MO278

Exposure of non-target prey and predators to anticoagulant rodenticides

A. Geduhn, Julius Kuehn Institute, Federal Research Centre for Cultivated Plants; A. Esther, JKI / Vertebrate Research; D. Schenke, Julius Kühn-Institute, Federal Research Centre for Cultivated Plants / Institute for Ecological Chemistry Plant Analysis and Stored Product Protection; J. Jacob,

Anticoagulant rodenticides (ARs) are the main management tool for the reduction of commensal rodents worldwide. However, ARs are toxic to all warm blooded organisms and can lead to wildlife exposure and poisoning. The details of the connection between primary exposure of non-target small mammals by direct AR bait consumption and secondary exposure of predators through uptake of contaminated prey are often unknown. In field studies we assessed the exposure of small mammals and estimated AR exposure risk for barn owls (*Tyto alba*) based on AR residues in small mammals during baiting campaigns on farms and the diet of barn owls in the farm environment. In addition, we screened barn owl spit pellets, liver samples of prey cached by barn owls, and carcasses of predators for AR residues to clarify the exposure pathway from bait to predator. Furthermore, we analyzed local parameters affecting AR exposure in red foxes on regional scale to identify spatial drivers of AR exposure in top predators. AR residue concentration of non-target small mammals was highest within 15 m of bait points and low concentrations were detected in animals caught at a distance of up to 87 m. *Apodemus* species and the shrew *Crocidura russula* regularly carried residues (sometimes at high concentration), whereas exposure in *Microtus* species was low. The exposure risk of barn owls was highest in autumn when owls increasingly preyed on *Apodemus* species and low in summer when owls mainly preyed on *Microtus* species. ARs were rarely found in spit pellets but were present in 13% of prey items collected from nest boxes. About 36% of predatory birds and owls and 60% of red foxes (*Vulpes vulpes*) that were sampled across Germany carried AR residues. In foxes, the presence of AR residues was correlated to the percentage of urban area and livestock density. The results demonstrate that AR exposure of non-targets occur more or less often depending on species and several environmental correlates incl. distance to bait points (small mammals), seasonal prey composition (barn owls), and livestock density (foxes). Knowledge about environmental drivers of non-target exposure to ARs can be used to adjust risk mitigation strategies. (this study was funded by German Federal Environment Agency grant #371063401)

MO279

Resistance of Norway rats (Rattus norvegicus) to anticoagulant rodenticides: Distribution in Germany and factors determining the spread

A. Esther, JKI / Vertebrate Research; I. Krämer, Julius Kuehn Institute, Federal Research Centre for Cultivated Plants; N. Klemann, Rodent research consultant;

A. Geduhn, S. König, Julius Kuehn Institute, Federal Research Centre for Cultivated Plants
Resistance to anticoagulant rodenticides used as biocides is known in the commensal rodent species, *Rattus norvegicus*, *R. rattus* and *Mus musculus*. Knowledge about resistance distribution and factors determining its spread are essential for an effective management with focus on mitigated risks to the environment. The polymorphism Tyr139Cys of the VKORC1-gen is the genetic marker of anticoagulant resistance in *R. norvegicus* in Germany. Effective management of resistant Norway rats is not possible with first-generation anticoagulants (warfarin, chlorphacinone, coumatetralyl) as well as bromadiolone and difenacoum. Nevertheless, because of their high toxicity the active substances flocoumafen, brodifacoum and difethialone should be used only in cases of detected resistance in order to mitigate environmental risks entailed with the use of these compounds. Rat samples have been collected since 1999 in the resistance area in Northwest Germany. On local scale we investigated both, the frequency of the resistance gene by ArmsPCR and the genetic distance using fragment length polymorphisms of nine single sequence repeat markers to determine the spread of Norway rats within the resistance area. We analyzed 189 individuals from two successive years and 13 farms. The analyzed rats showed high site fidelity; places of capture were identically to the place of origin. The total population could be virtually subdivided into eight units with different degree of gene flow. Geographic structure rather than spatial distance was found to structure the rat population. While most farming sites along a small creek were found to be populated by rats of the same clustering unit farms with increasing distance to the creek differed markedly. Three completely isolated clustering units were detected without gene flow to the remaining investigated population. Virtual subdivided units could be correlated to Tyr139Cys allele distribution. While Tyr139Cys was present at all sites it occurred disproportional frequent in the isolated units. In consequence, the applications of the most potent anticoagulants are mandatory to combat resistant infestations. Knowledge about rat migration will allow targeted applications of active substances appropriate to the risk of resistance occurring in order to mitigate environmental risk where the exposure of non-target animals cannot be completely avoided.

Life Cycle Data and Modeling Developments - From Data Collection to Usage (P)

MO280
Life Cycle Assessment of bio-based solvents for paint and coating industries
C. Bories; N. Guzmán-Barrera, J. Peydecastaing, INP-ENSIACET / Laboratoire de chimie agroindustrielle LCA; I. Etxeberria, Tecnalia / Division Construction; E. Vedrenne, C. Vaca Garcia, S. Thiebaud Roux, INP-ENSIACET / Laboratoire de chimie agroindustrielle LCA; C. Sablayrolles, INP-ENSIACET
Keywords: Solvents, Bio-based products, Environmental impacts, Sustainability
The global consumption of solvents is significant, with almost 28 million metric tons consumed in 2012 (Linak and Bizzari, 2013). The paints and coatings sectors are the main solvent consumers. This demand is predicted to increase by 2.9 % per year until 2019 (Ceresana, 2014). Nowadays, the solvents used in the paint and coating industries are currently produced from petrochemical sources. In the context of sustainable development, the replacement of traditional solvents by new green alternatives has to be studied. The ECOBIOFOR project, developed by a consortium of 11 European partners from 6 different countries, will help the transition of European paints and coatings industry from petrochemicals to bio-based products. The main objective of the ECOBIOFOR project is to develop novel bio-based solvents from renewable building blocks thanks to easier chemical or biotech transformations processes. In parallel to the syntheses development, a Life Cycle Assessment (LCA) of these new bio-based transformation processes is considered, using the ILCD method with some improvements, in order to assess their potential environmental impacts and so select the best-developed options. These new pathways are also compared to traditional petrochemical processes. After we defined the goal and scope of this LCA study, difficulties have been encountered on the data collection due to confidentiality issues and lack of data, especially for the chemicals in the Ecoinvent database. Methods to overcome these difficulties have thus to be developed from the point of view of the foreground and background data. Therefore, data could be obtained either from specific collection (directly from the manufacturers or in the R&D laboratory), by using proxy to model the considered molecule by a similar one already available in the databases or finally by semi-specific modelling, *ie*. reconstructing the synthesis pathway through retrosynthesis to obtain building blocks available in Ecoinvent v3. **References :**

MO281
Conversion of international environmental reporting data to LCA data for SCP
T. Rydberg, L. Hallberg, . SjÃdin, S. Ryding, IVL Swedish Environmental Research Institute
Consumption patterns have shown to increase the use of natural resources for the production of goods and services. A national project has been set up to provide support to Swedish authorities (notably the Swedish Environmental Protection Agency and the Swedish Agency for Marine and Water Management) to gain a better understanding of the reasons for why some environmental problems are difficult to forecast - thereby making them difficult to mitigate by conventional methods - with a special focus linked to Sustainable Consumption and Production (SCP). The theoretical parts, which cover a major portion of the overall work, include a methodological development on a scientific basis where long-term national monitoring data provided by the Consortium for Environmental Data reporting in Sweden (SMED), in various contexts such as the Industry Emissions Directive (IED), the UNFCCC, and others, are subject to assessments on how such data can be converted into LCA-based information. Such an assessment will primarily include two essential aspects ♀_ one dealing with a number of technical considerations for allocation and other LCA aspects, the other with non-technical aspects, e.g. the proper use of confidential data. This part of the project will also explore how SMED data could be used for trend analysis enabling identification of key pollutant emission sources as an input to a deeper understanding of why some environmental quality objectives, specifically those related to SCP, are hard to fulfil. The practical and operational parts will focus on synthesis and implementation of results, in which conclusions are drawn on how the SMED work can be better linked to the work related to the Swedish environmental goals, as well as providing some perspectives for suggesting additional needs of legislative and other means for better control of SCP. This part will also focus on international outreach, in which the key focus will be to provide a future input to the UN work on establishing a "Global Network for Interoperable LCA Data Bases (GlobaLCAccess)", and link these activities to European and international standardisation work.

MO282
LCI data sets for up-stream processes of fossil energy for Germany today and 2030
C. Mohr, Technische Universitat Darmstadt / Material Flow Management and Resource Economy; S. Weyand, Institue IWAR Chair of Material Flow Management and Resource Economy; L. Schebek, TU Darmstadt / Material Flow Management and Resource Economy
The German "Energiewende" (Eng. energy transition) aims at enhancing the share of renewable energy carriers in order to mitigate Green House Gas emissions. Mitigation is calculated against the reference of fossil energy sources such as crude oil and natural gas. However, environmental impacts of extraction of fossil energy carries also change in the course of time due to technological performance but also due to an increasing use of unconventional sources. For a realistic estimate of national GHG balances in different energy scenarios, data for up-stream processes are most crucial: Whereas the environmental impacts of the combustion technologies mostly are well-known, the extraction of fossil fuels receives little attention in life cycle assessment (LCA) studies (Bouman *et al*., 2015). This translates into the lack of data availability showing changes of conventional and unconventional extraction technologies in LCA databases. The performance of high quality life cycle assessments requires life cycle inventory data representing the current state of technology. To this end, this study analyses environmental impacts of current production technologies of petroleum and natural gas. Life cycle inventory datasets describing the current production of crude oil and natural gas in various regions are provided and compared with older datasets produced in 2000. The production regions examined are those which provide Germany with crude oil or natural gas. Furthermore, in order to analyse the future global warming potential (GWP) regarding the production of 1 kg crude oil and 1m3 natural gas for usage in Germany, scenarios for 2030 are developed. The LCAs are generated according to ISO 14040 and ISO 14044. For the bulk of oil producing regions, a decrease of GWP compared to 2000 is identified. Simultaneously, the GWP of natural gas production has increased in all examined regions of production. Based on the scenarios, future GWP of natural gas production for Germany will be higher than today. The results of the scenarios for the crude oil production are less distinct. The results range from nearly constant GWP to increased GWP. Taking into account the current trend for decreasing GHG emissions during oil production, even a sinking GWP might be possible.

MO283
Assessing the environmental improvement of new technologies in the detection of pathogens in drinking water - the wider impact of the AQUAVALENS project
C. Torres, Universitat Rovira i Virgili / Departament dEnginyeria Química; F. Castells, Universitat Rovira i Virgili / Chemical engineering department; M. Figueras, Universitat Rovira i Virgili
Life Cycle Assessment can be applied to a wide range of case studies considering that it can be seen as a philosophy for undertaking the countable procedure of all pollutant exchanges between the system analyzed and the environment. This system can take the form of a variety of activities, services and products, from an entire industrial sector of a country to any particular action that a person can perform. The LCA practitioner must face the challenges posed by the peculiarities of each system, adapting the assessment to the demands on data availability, uncertainty of the input data, resolution

of the model, necessary assumptions, sensitivity to unsettled parameters, etc. In the presented study we analyze the consequences of adopting decisions on the mentioned features in the design of the LCA models used. The systems to be evaluated are the novel platforms developed under the project AQUAVALENS for the detection of pathogens in drinking water. The aim of the project is to enable the water system managers, food growers and manufacturers to better control the safety of their water supplies by using newfangled technologies that integrate sample preparation and detection into a single platform. The Carbon Footprint calculation of these platforms will be used to determine their sustainability as part of final objectives of the project, which include the protection of human health, improving the effectiveness of Water Safety Plans, adaptation to climate change and control of outbreaks of infectious diseases. The challenges of developing a LCA of the systems under study rely on the difficulty for setting a high number of parameters related, on the one hand, with the platform manufacturing and , on the other hand, with the protocols and procedures to use them. The complexities have their origin in the diversity of platforms, manufacturers and potential users, which make valid the saying that there is more than one way to skin a cat. This variety have forced us to perform the study in a iterative way, where questionnaires and model drafts have consecutive introduce the needed input data from the most general to the smallest detail so that each model was refined to obtain a degree of uncertainty consistent with the objectives of the study. Particularly, the decisions and assumptions made were based on robust uncertainty and sensitivity analyses.

MO284
Prospective performance indicators of electricity production in Spain
D. García-Gusano, Instituto IMDEA Energía / Systems Analysis Unit; D. Garrain, CIEMAT / Energy Energy Systems Analysis Unit; D. Iribarren, Instituto IMDEA Energía / Systems Analysis Unit; H. Cabal, CIEMAT / Energy Department Energy Systems Analysis Unit; J. Dufour, Instituto IMDEA Energía / Systems Analysis Unit
Although environmental modelling methodologies such as Life Cycle Assessment (LCA) are well-known tools for the analysis of sustainability issues, there is a gap in managing the time dimension. Many studies carry out assessments assuming predefined systems concerning the future or use roadmaps from the literature. This work involves a detailed LCA study from a consequential perspective by using a national energy systems optimisation model, TIMES-Spain. This methodological linkage strengthens the discussion on how the electricity production mixes should be built in the future according to key prospective performance indicators. TIMES-Spain, built with the TIMES energy optimisation model generator developed by ETSAP Implementing Agreement of the International Energy Agency, provides energy-related technology mixes for satisfying the demand of energy services in all economic sectors (industry, transport, etc.) under different assumptions. A couple of scenarios were implemented: a Business as Usual scenario “BaU” with restrictions from European Directives, and an exploratory scenario “80%” enforcing an 80% reduction in the total Spanish CO_2 emissions by 2050 with respect to 2005 levels. The evolution of the electricity production mixes from the optimisation process shows that the scenario “BaU” results in a major presence of natural gas cogeneration plants in the long term, whereas the scenario “80%” prioritises wind and biomass options. LCA computation was performed for the set of existing and new technologies. Besides, a LCA/TIMES harmonisation procedure was carried out avoiding a potential double counting of emissions. In this regard, existing processes in TIMES-Spain were adapted to include a fraction of the burdens linked to infrastructure by assuming a residual lifetime according to the year of installation. The evolution of ten life-cycle indicators (from ILCD 2011 and ReCiPe methodologies) shows global reductions in the long term ranging from 21% for Ozone Depletion to 85% for Acidification in the scenario “BaU”, and reaching up to 87% for Acidification in the scenario “80%”. Nonetheless, Abiotic Depletion grows significantly due to the rare metals required in the production of solar cells, highly present in the future mix. Energy systems modelling is found to be a valuable tool to perform prospective LCA studies in the field of energy, adding the time dimension to the sustainability assessment.

MO285
Lessons Learned in Developing an Environmental Product Declaration Program for the Asphalt Industry in North America
A. Mukherjee, Michigan Technological University / Civil Environmental Engineering; H. Dylla, National Asphalt Pavement Association
The objective of this presentation is to report the technical and organizational challenges involved in the development of the North American Environmental Product Declaration program for asphalt mixtures. It explores how differences in stakeholder priorities and perspectives, in the pavement construction industry, directly shape the Product Category Rules (PCR) defining the program. The primary challenge identified is how to ensure technical rigor of the underlying LCA, while recognizing the interests of the stakeholders and ensuring the delivery of a program that is effective. The presentation discusses how technical issues regarding system boundary choice, data use and allocation presented challenges for the PCR Development Working Group accounting for different stakeholder interests. Insights into the discussions that informed the PCR development are provided.

LCAnet.de - A new network for LCA practitioners in Germany
B.M. Zimmermann, LCAnet.de; J.F. Peters, KIT Karlsruhe Institute of Technology / Helmholtz Institute Ulm HIU; W.D. Bulach, Oeko-Institut Darmstadt; S. Weyand, Technische Universitat Darmstadt / IWAR Chair of Material Flow Management and Resource Economy
LCA networks provide contacts and allow for exchange of knowledge and questions within the LCA community. They can be an extremely helpful address for solving problems and obtaining information about recent developments, new publications and upcoming workshops, especially for new practitioners. While there are several important LCA networks on international level or in other regions, there is little local activity in Germany. LCAnet.de is a recently founded non-profit organization dedicated to the exchange of knowledge among – especially young – LCA practitioners. It aims at building up a decentralized structure with several regional nodes in Germany. This should keep distances between the actors short, allowing for direct communication and shorter, cheaper and environmental friendly travels to workshops. LCAnet.de's first node is in the city of Karlsruhe reaching from Freiburg in the south to Darmstadt in the north. LCAnet.de is an integrative network, open for everyone who is working in a LCA context within the network's regions. Therefore the language of communication is English. By distributing organizational tasks among the network's members, LCAnet.de can run on a small budget. Consequently member fees are very low, and participation in workshops is either free or inexpensive. This eases the access for people who are not able to pay considerable member fees such as students, PhD-candidates or professionals who are hardly connected to the academic LCA community. LCAnet.de provides a web page with relevant news and a forum for addressing specific questions to the community. The core activity of LCAnet.de is the organization of regional workshops at least twice per year. Each workshop addresses a single, LCA-related topic, aiming at learning, discussing, problem solving, method developing and networking. This poster presents the non-profit organization LCAnet.de, provides information about its principal goals, how to become member and about the services and networking activities provided by the network. It invites especially young, but also experienced LCA practitioners to join and to actively contribute to the development of this initiative.

MO287
Ecospold 02 - ILCD: mapping and format converter
S. Fazio, EC-JRC / Institute for Environment and Sustainability; F. Mathieux, EC JRC IES; G. Blengini, European Commission DG Joint Research Centre; A. Ciroth, GreendeltaTC GmbH; S. Sala, European Commission - Joint Research Centre / Sustainability Assessment unit; C. Rodríguez, GreenDelta GmbH
In a recently completed project carried out for the Joint Research Centre (JRC) of the European Commission, GreenDelta updated the International reference Life Cycle Data system (ILCD) reference elementary flow list. Basing on the existing mapping file available in GreenDelta’s open LCA format converter, the ILCD flowlist has been revised and updated, in collaboration with JRC, in order to cover all the elementary flows available in EcoSpold02 nomenclature. For the EcoSpold02 flows not mappable in the ILCD reference flow list, new flows have been added to the ILCD lsit. Almost 400 new flows have been created, and more than 3400 have been mapped, and the nomenclature has been further investigated also accounting for the new needs of the upcoming Environmental Footprint (PEF and OEF) scheme, which is now in the pilot phase, under the supervision of DG Environment. The project has been funded by JRC within the institutional activities, therefore the converter was developed only for the conversion from Ecospold02 to ILCD and not vice-versa, since the other formats and nomenclature are not officially adopted or endorsed in EU Policy. However, the results of the project are now available also in the framework of the international cooperation for the Global Network of interoperable LCA databases, led by UNEP, where the aim is to expand the mapping also to other format and nomenclature systems, and to enhance the converter in order to allow multi-directional convertibility.

Improving the usability of ecotoxicology in regulatory decision-making: findings from a SETAC Pellston® Workshop (P)

MO288
Updating Environmental Quality Standards using REACH disseminated data: an illustration of transfer of knowledge between policies
G. Deviller, CJExpertPOPs
Article 16 of the Water Framework Directive (WFD, EC 2000) sets out the strategy against chemical pollution of surface waterbodies. The chemical status assessment is used alongside the ecological status assessment to determine the overall quality of a waterbody. The Environmental Quality Standards (EQSs) Directive (EC 2008a) establishes concentration limits for 33 Priority Substances and 8 other pollutants. EQSs were derived for the Priority Substances at a European level and are used to assess the chemical status of water bodies in all Member States. In addition, the WFD establishes the principles to be applied by

the Member States to develop EQSs for Specific Pollutants that are 'discharged in significant quantities'. Compliance with EQSs for Specific Pollutants forms part of the assessment of ecological status. Derivation of EQSs is based on (eco)toxicological data on organisms that are relevant for the identified protection goal: the pelagic organisms for waters (fresh and marine), the benthic organisms for sediments (fresh and marine) and mammals/birds for secondary poisoning. Many of the EQS that have been derived up to now have used peer-reviewed data and in many cases data gaps were observed for one or more compartments. However, it is recognised that the risk assessment paradigm on which the EQS derivation is based could lead to unworkable and/or unrealistically low EQS values in case of data lacking (Technical Guidance for deriving EQSs, 2011). With REACH entering into force, many studies have been performed by industry in order to comply with their regulatory obligations. The dissemination of data of registered dossiers on ECHA's publicly available website has given considerable opportunities to improve our knowledge of the substances properties and to reassess previous work like EQS derivation. This presentation will show how REACH disseminated data have been assessed for EQS derivation purposes (relevance and reliability) and if these new data could decrease the uncertainties attached to the existing EQS and finally improve the global assessment of the chemical status of European waters.

Innovative techniques for monitoring chemicals in the environment (P)

THE IMPACT OF β-BLOCKERS ON THE SOIL MICROBIAL PHYSIOLOGICAL DIVERSITY

M. Pino, San Jorge University / Facultad ciencias de la salud; S. Muñiz, Pyrenean Institute of Ecology (CSIC); J. Val, San Jorge University; E. Navarro, CSIC - Spanish National Research Council / Biodiversity conservation Ecosystems Restoration

Pharmaceuticals and their metabolites reach the terrestrial ecosystems through the application of wastewater and contaminated biosolids to agricultural soils. There, these products may impact the microbial community. We have evaluated the effect of six widely consumed β-blockers on soil microbial communities from an ecological farming crop field using the community-level physiological profile –CLPP-. This method is based on the rate of carbon substrate degradation on microplates (Biolog Ecoplates®). The impact of the pharmaceuticals has been assessed by comparing the Averaged Well Color Development –AWCD- of each treatmente, as an integrative indicator of the physiological ability of the microbial community for degrading all carbon sources. Nadolol provoked a slight decrease in the AWCD compared to control. On the other hand, a stimulatory effect was observed for the other β-blockers. The Shannon diversity índex (H) was used to evaluate the physiological diversity of the microbial communities. The soils treated with propranolol ($p< 0,05$) and metoprolol ($p< 0,01$) presented a significantly lower physiological diversity. The β-blockers also significantly decreased the degradation of polymer carbon and carboxylic and ketonic acids sources and significantly increased the amines/amides. No differences were detected in the use of carbohydrates and amino acids, except for the atenolol that showed a significant increase ($p< 0,05$) in the use of amino acids. Results shown that pharmaceuticals on soil microbial communities, at environmentally relevant concentration (around 100 mg/Kg), altered key ecosystem functions as that of the carbon cicle.

TU002

Eco-toxicity and human toxicity impact in urban area: case of accumulated trace metal air pollution analysis on cemetery mosses in Paris city

A. Yalaltdinova, Tomsk Polytechnic University / Geoecology and Geochemistry; J. Kim, University of Technology of Troyes / Department of Humanities Environment Information Technology CREIDD; M. Natali, IENI-CNR; A. Zanella, University of Padua / TESAF; A. Rankovic, J. Lata, University Pierre et Marie Curie / Institute of Ecology and Environmental Sciences

The monitoring of global atmospheric pollution in urban and peri-urban areas is in a crucial phase where expectations of society in terms of environmental issues often exceed the capacity of integrative measures to track pollutants in the long term. Mosses are useful ubiquitous accumulation bio-monitors and as such were used for European surveys. Furthermore, anthropogenic emissions (e.g., heavy metals) being closely related to ecosystem and human health, integrative risk assessment is also of a major interest in citizens' expectations. In this study, we tested the hypothesis that cemeteries are appropriate sampling sites to evaluate moss accumulation of air pollutants in urban areas, and that the USEtox impact assessment model is useful to provide relevant eco-toxicity and human toxicity impacts. For this purpose, we sampled mosses growing on gravestones in 21 urban and peri-urban cemeteries in the Parisian metropolitan area. We focused on *Grimmia pulvinata*, a species abundantly found in all studied cemeteries. We quantified 19 elements with TXRF-SSM method. For eco-toxicity and human toxicity impact and mapping, the use of USEtox method of life cycle impact assessment and its characterization factors allowed to characterize factors and categories (human toxicity and ecotoxicity) related to trace metals in air emissions. We show that enrichment factors for some markers of road traffic (e.g. Pb, V, Zn, Cr) indicate that the highest polluted cemeteries were located near the highly frequented ring road of Paris and under the influence of prevailing winds coming from the Southwest. The sites with the lowest pollution appeared in peri-urban cemeteries, adjoining forest or farming landscapes, but also in large and relatively woody cemeteries located in the centre of Paris. The calculation and mapping of the accumulated eco-toxicity and human toxicity impacts allowed showing the distribution of highest and lowest polluted areas in complex urban fabric as Paris area. Observed differences between environmental and human toxicity distributions show that we can expect more spatial variability of toxicity impact even in densely urbanized areas that usually thought.

TU003

E-Board - a new in situ method for assessing the reproduction-related traits of chironomids: proof of concept and potential perspectives of use

B. Ferrari, Ecotox Centre CH; J. Faburé, AgroParisTech / UMR ECOSYS INRA Université ParisSaclay

Further progress in the development of reliable biomonitoring strategies requires to better link effects in aquatic ecological systems to ambient contaminations. Among existing tools, *in situ* bioassays using caging method represent an interesting way to achieve this challenge. However, elaboration of adapted exposure chambers and suitable operating procedures is still required, particularly to assess ecological relevant traits such as those related to the reproduction. In such context, we developed a new device (Emergence board - E-Board) which allows assessing in rivers the development of the *Chironomus riparius* species from the early fourth instar larvae to the adult stage. The system is based on the hypothesis that chironomid larvae mainly feed on freshly deposited suspended matters that represent the major exposure route to contaminants for them. The system acts as a suspended matter trap floating in the subsurface of the water equipped of an emergence trap for catching chironomid adults. The system was tested in actual field conditions. Its easy handling allowed obtaining data which demonstrated its applicability for assessing the development of the chironomids. Moreover, by adapting energy-based models specifically developed in the laboratory for the species *C. riparius*, we were able to predict the growth pattern and the emergence of chironomids in real environmental conditions. The method offer the possibility to follow ecologically relevant responses on sensitive life stages or periods for individuals which are difficult to take into consideration in conventional community surveys and which are crucial to infer impacts at population level. The E-Board represents thus a promising new in situ tool in perspective of evaluation of the quality of the ecosystems.

TU004

Development of sensor based on optical fibre for identification of chemical parameters in surface water

B. Obrovski, Faculty of Technical Sciences, Novi Saf / Department of Environmental Engineering; J. Bajić, Faculty of Technical Sciences Novi Sad / Department of Power Electronic and Telecommunication Engineering; M. Vojinovic MIloradov, Faculty of Technical Sciences University of Novi Sad / Department of Environmental Engineering and Occupational Safety and Health; M. Vojinovic Miloradov, M. Djogo, University of Novi Sad Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; B. Batinić, Faculty of Technical Sciences Novi Sad / Department of Power Electronic and Telecommunication Engineering; I. Mihajlovic, Faculty of Technical Sciences University of Novi Sad; M. Zivanov, Faculty of Technical Sciences Novi Sad / Department of Power Electronic and Telecommunication Engineering

Permanent monitoring of contaminants that can disturb the quality of surface water is required, due to increased environmental pollution from anthropogenic sources. Standard laboratory methods revealed certain disadvantages relating to the high cost, complexity of analysis and the possibility of losing the desired analyte caused by human error in sampling, storage and transport of samples. Fiber optic sensors (FOS) are convenient technology for monitoring of surface and ground water and to provide continuous and real data about the current state of water bodies. FOS have certain advantages over conventional methods such as: simple design, small size, possible use in hazardous chemical environments that can damage the measuring equipment, can be used for remote sensing and in distant areas, safety because of the low optical power and the absence of electric current at the sensing point and resistance corrosion. This paper presents a prototype of colour FOS for detection of different inorganic parameters in surface water. Implemented sensor converts the RGB color model to HSV color model and based on the color intensity of the sample determines the concentration for parameters of interest. The concentration of the chemical parameters is calculated by introducing the obtained values of H (Hue), V (Value), S (Saturation) in transfer function. Colour FOS based on HSV model was designed for the determination oforthophosphate, nitrite, sulfate, $Cr^{6+}_{(aq)}$ and total chlorine in surface water samples. Results obtained with the applied sensor are compared to the results obtained with laboratory analysis to prove the efficiency of the device. FOS has proven to be very suitable for use in the laboratory under controlled conditions as low-cost solution to replace expensive standard equipment. Future research should be focused on performance improvement and on increasing the sensitivity of the device, which will be achieved by choosing better quality LEDs with a wider wavelengths range. Keywords: fiber optic sensors, low-cost measurements, surface water Acknowledgement: The research has been supported by Ministry of Education, Science and Technological Development of Republic of Serbia under project Development of methods, sensors and systems for monitoring quality of water, air and soil, III43008.

TU005

FROM TOXICOLOGICAL BIOASSAY AND CHEMOMETRICS ANALYSIS TO A RAMAN SPECTROSCOPY MULTIPARAMETRIC BIOSENSOR

M. Bittel, Universite de Nantes / GEPEA CNRS UMR CBAC Laboratory; A. Assaf, S. Jouanneau, University of Nantes / GEPEA CNRS UMR CBAC Laboratory; C. Cordella, INRAAgroParisTech / INRA UMR GENIAL; M. Durand, University of Nantes / UMR CNRS GEPEA CEBAC Laboratory; T. Gerald, University of Nantes / Microbiology

In the field of toxicological bioassays, the toxicity assessment of a pollutant or a mixture on living organisms is often based on the observation of a single physiological parameter (e.g.: bioluminescence inhibition, cellular death, enzymatic activity). The monoparametric aspect of such bioassays limits their performance in terms of specificity and sensitivity. They need to be associated in order to provide a global toxicity measurement, and lead to the multiplication of the implemented tests. In this context, the latest progresses in the Raman spectroscopy open new research perspectives on fast method of observing metabolic responses against toxic agents. Indeed, each spectrum is made of more than 2700 data points which represent a molecular fingerprint of the observed samples. This multiparametric approach provides an overview of the physiological changes caused by the pollutants. Thus, the comparison of spectra from bacteria exposed or not, is used to define a “signature” for a given toxic effect and overcome the limitations of other biosensor techniques. Moreover, the physiological spectral fingerprint is both rich and complex. Consequently, to be properly analyzed it needs complex chemometrics methods. In this study, statistical multivariate analyses have been implemented to highlight the differences between spectra of the bacteria *Escherichia coli* exposed to various increasing arsenic concentrations. The results show both a dose-response and an exposure time effect of the arsenic on *E. coli* cells. Furthermore, the fine analysis of the Raman spectroscopy fingerprints permits to identify the cellular macromolecules impacted by this chemical. The highlighted changes are in accordance with the expected toxic effects. In the future, a toxic signature of pollutants and a more precise overview of their metabolic target might thus be identified by the Raman multiparametric observations of toxic effects on microorganisms’ metabolism coupled to chemometrics tools.

TU006

Application of LC-APCI-qTOF-MS for simultaneous analysis of short-, medium- and long-chain chlorinated paraffins in technical and environmental samples

L. Schinkel, ETH Zürich/Empa / Laboratory for Advanced Analytical Technologies; N. Heeb, A. Gerecke, Empa Swiss Federal Laboratories for Materials Science and Technology / Laboratory for Advanced Analytical Technologies; S. Matam, Empa Swiss Federal Laboratories for Materials Science and Technology / Laboratory for Materials for Energy Conversion; K. McNeill, ETH Zurich / Institute of Biogeochemistry and Pollutant Dynamics; C. Bogdal, Institute for Chemical and Bioengineering ETH Zürich / Institute for Chemical and Bioengineering

Chlorinated paraffins (CP) are high production volume chemicals (1 Mio t/a in 2009) used as extreme pressure additives, plasticisers and flame retardants. They are of concern due to their persistence, bioaccumulation potential and the limited information on their environmental fate and toxicity. Analysis of CPs in environmental samples is a nightmare due to the large number of congeners and isomers (chain length: C_{10}-C_{28}, Cl-degree: 30-70%) and the lack of suitable standards. Recent analytical methods mainly focus on short-chain CPs (SCCPs). SCCPs are currently discussed to be classified as persistent organic pollutant by the Stockholm Convention Review Committee. Thus, a shift in production and emission to medium- and long-chain CPs (MCCPs and LCCPs) is expected, requiring respective analytical methods. Most studies on CPs apply gas chromatography (GC) with mass spectrometry (MS). However, GC is not suitable for analysing CPs with increased chain length due to their low volatility. Recently, Bogdal et al. 2015 (Anal. Chem. 87, 2852-2860) developed a method overcoming the need for separation using direct liquid injection and focussing on accurate mass determination. They apply atmospheric pressure chemical ionisation (APCI) under chlorine-enhanced conditions in negative ion mode followed by quadrupole time-of-flight (qTOF) MS. Their method allows rapid (< 1min) and simultaneous analysis of SCCP, MCCP and LCCP, featuring increasing sensitivity with increasing chain length. The present study investigates how different CP congeners compete for the available chloride. Liquid chromatography (LC) was applied to partially separate CPs. The developed LC-method was able to overcome drawbacks of the direct injection such as matrix interferences and co-elution of analytes with similar masses. The optimised method has been applied to technical and environmental samples and compared to direct injection. Homologue-specific patterns were validated using a carbon skeleton method which relies on the complete hydrodechlorination of CPs to respective alkanes. Corresponding results will be presented. This LC method is the first chromatographic method for simultaneous analysis of SCCP, MCCP and LCCPs since 2004 and it is the first LC method based on high-resolution MS for CP analysis applied to environmental sample.

TU007

Monitoring of pesticides in air - sampling technique implications

E. Paulsson, O. Jonsson, Swedish University of Agricultural Sciences (SLU) / Department of Aquatic Sciences and Assessment; J. Kreuger, Swedish University of Agricultural Science / Centre for Chemical Pesticides

Pesticides applied on agricultural fields can enter the atmospheric compartment due to volatilization. Depending on e.g. compound intrinsic properties and climatic conditions pesticides can thus be subjected to short- or long-range atmospheric transportation following application. Monitoring studies frequently demonstrate occurrence of currently used pesticides in the atmosphere, including trans-boundary transport. However, less is known on the importance of the collection procedure of air-born pesticides in order to enhance interpretation of the transport processes involved. Air samples were collected during 2010 – 2012 in a forested area in the south of Sweden, with little agricultural activities in the vicinity. Using high-volume sampling air was pumped, during 5-7 days, through a glass-fiber filter followed by polyurethane foam (PUF) and a hydrophobic crosslinked polystyrene copolymer resin (XAD), in a PUF-XAD-PUF-sandwich for simultaneous sampling of both particle bound and gas phase pesticides. The filter and the three adsorbents were Soxtec extracted separately to investigate the distribution of pesticides. The samples (n = 34) were analysed for 67 pesticides on GC-MS. Overall, a total of 43 pesticides were detected in the air samples. The most frequently detected (100% of the samples) were lindane, α-HCH, HCB, α-chlordane and γ-chlordane, i.e. pesticides banned since more than a decade within the EU. The pesticide found in the highest concentration was prosulfocarb at 13 ng/m^3. On the filter 25 pesticides were identified, most of them currently being used in Sweden. Some of these were only detected on the filter. The first PUF contained 81% of the total pesticide concentration and out of the 33 pesticides detected 19 of them were not approved for use in EU. The XAD and the second PUF generally contained low amounts of a few substances also found in the first PUF. Of all 43 detected pesticides only dichlobenil, α-HCH, heptachlor, HCB and trifluralin gave a breakthrough of more than 30% from the first PUF to the XAD and second PUF. The XAD was essential for capturing a few very volatile, obsolete pesticides, but generally the first PUF was efficient enough to adsorb pesticides in gas phase at environmental relevant concentration levels. For an accurate estimate of the pesticide concentrations in air, especially for currently used pesticides, it is vital to include the particulate phase by adding a filter material in the collection procedure.

TU008

Spatio - temporal quantification of gadolinium and iodide complex uptake in zebra fish embryo

S. Wagner, Helmholtz Centre for Environmental Research GmbH - UFZ / Department of Environmental Geoscience; F. Blaschke, Helmholtz Centre for Environmental Research GmbH UFZ; H. Stärk, Helmholtz Centre for Environmental Research GmbH UFZ / Analytical Chemistry; T. Reemtsma, Helmholtz Centre for Environmental Research; E. Küster, Helmholtz Centre for Environmental Research, Dept.Bioanalytical Ecotoxicology / Bioanalytical Ecotoxicology

Key parameters for adverse effects of chemicals to organisms are chemical uptake by and distribution within the organism leading to the “internal exposure” as pivotal factor for biological effects of chemicals. Recently the zebra fish embryo (ZFE) has been suggested as a model organism to observe potential toxicological effects of anthropogenic compounds. In order to correlate toxicological effects in the ZFE with uptake and distribution data analytical methods have to be provided. In future such correlations are required as input for toxicokinetic/toxicodynamic models which will be able to predict effects of chemicals on ZFE. These predictions are an important component of risk assessment approaches. Quantification of uptake based on internal concentration analysis can be regarded as state-of-the-art. Compounds such as gadolinium and iodide complexes used as contrast agents were selected as examples to study the uptake and the distribution in the ZFE because of their increasing application. This work aims at developing analytical methods to provide internal concentration data as well as compound distribution data in ZFE by means of laser ablation hyphenated to inductively coupled plasma mass spectrometry (LA-ICP-MS). Exposure studies with ZFE and gadolinium and iodide complexes are presented. Internal concentration and compound distribution in ZFE were determined after 96 h of exposure. Internal element concentrations were quantified by ICP-MS. LA hyphenated to ICP-MS was applied to map gadolinium and iodide distribution in cross-section of ZFE. Calibration of LA-ICPMS instrumentation was done by agarose standards with known gadolinium and iodide concentration. Exposure studies with iodide compounds (iohexol, iomeprol, iopromide, iopamidol, amidotrizoic acid) revealed a compound uptake between 10 and 18% of the external concentration. Uptake of the investigated gadolinium complexes (Gd-Dota, Gd-Dtba, and Gd-EOB-Dtba) was in the range between 1 and 3% of the external concentration. Qualitative spatial resolved analysis indicated elevated iodide concentrations in the ZFE cross-sections. For both, iodide and gadolinium complexes quantitative distribution data will be discussed. The presented method provides a significant progress towards quantitative data which is required for process understanding and risk assessment. Additionally the analytical methodologies presented here can be transferred to other elements which are accessible to ICP-MS detection.

TU009

Determination of short-chain and medium-chain chlorinated paraffins in fish tissues by gas chromatography coupled to high-resolution time-of flight mass spectrometry

P. Labadie, CNRS; K. Le Ménach, CNRS / Université de Bordeaux; M.P. Babut, Irstea / Water; H. Budzinski, University of Bordeaux / UMR EPOC LPTC

Short-chain chlorinated paraffins (SCCPs) and medium-chain chlorinated paraffins (MCCPs) are chlorinated alkanes of variable chain length and chlorination degree. They constitute a complex mixture of straight and branched compounds (>10,000), used in a wide range of applications as lubricants in metal working or in the leather industry, plasticizers or flame retardants as well as in sealants, paints and coatings. Both SCCPs and MCCPs are considered to fulfill the PBT criteria (persistent, bioaccumulative and toxic chemicals) since they exhibit high bioaccumulation factors in fish as well as elevated acute toxicity towards aquatic biota. As a matter of fact, SCCPs have been proposed for listing under the Stockholm Convention on Persistent Organic Pollutants. Although Low Resolution Mass Spectrometry (LRMS) operated in Electron Capture Negative Chemical Ionization (ECNI) is frequently used for the determination of SCCPs and MCCPs, the preferred analytical method is High Resolution Mass Spectrometry (HRMS), usually performed with a magnetic sector analyzer. This technique minimizes interferences from other contaminants and between SCCPs and MCCPs; it also enables the quantification of specific homologue groups (i.e. identical chain length and number of chlorine atoms). Over the years, High Resolution Time of Flight (ToF) and Orbitrap MS technologies have become available in numerous laboratories; these techniques, however, have not been fully explored for the determination of SCCPs and MCCPs in environmental samples. Thus, the aim of the present work was to develop a simple method for the determination of SCCPs and MCCPs in fish tissues, based on a single-step adsorption chromatography clean-up followed by analysis using gas chromatography coupled to ToF MS. The validated and optimized method was applied to the determination of SCCPs and MCCPs in the fillets of selected fishes from the Rhône River basin (South Eastern France). The target species was the Common barbel (*Barbus barbus*), a typical benthic feeder widely used for biomonitoring purposes in the European Union. *Acknowledgements* - This study was undertaken with the financial support of ONEMA, in the frame of the Investments for the future Programme (Cluster of Excellence COTE, ANR-10-LABX-45). CPER A2E (Aquitaine region and FEDER (Europe is moving in Aquitaine with the European Regional Development Fund (FEDER)) is acknowledged for financial support.

Performance of polyethylene passive samplers to assess DDx bioaccumulation in freshwater mussels

R. Borrelli, Renewable Energy & Environmental R&D Center, Istituto eni Donegani / Corporate; A. Oldani, F. Vago, Renewable Energy & Environmental R&D Center, Istituto eni Donegani; I. Verginelli, R. Baciocchi, University of Rome Tor Vergata / Department of Civil Engineering and Computer Science Engineering; S. Sforzini, University of Piemonte Orientale / Department of Sciences and Technological Innovation DiSIT; A. Viarengo, University of Piemonte Orientale / Department of Sciences and Technological Innovation; L. Zaninetta, Syndial / Environmental Remediation; P. Gschwend, MIT / Department of Civil and Environmental Engineering

Contaminants in the aqueous environment are present as dissolved, colloid-bound, and sediment-associated forms. The distribution of contaminants between these phases is a central issue as it strongly influences the sediment and water quality. In the past, sediment quality criteria were set using a simple equilibrium partitioning (EqP) approach seeking to relate dissolved and sorbed contaminants. However, this approach does not account for different aspects such as colloid speciation and specific sorption effects, that may dramatically change environmental impacts. Hence, in the last decades great attention was focused on new methods that can allow us to account for these issues when defining the quality of a sediment. Among these, the use of passive sampling is becoming an attractive option, as this method allows direct estimation of the pore water concentration of a chemical, i.e. a metric that reveals the bio-available fraction. In this work, we used passive samplers to assess the bioavailable forms of DDx in sediments collected from a lake located in northern Italy; the results were compared with those obtained by exposing the freshwater mussels, *Unio pictorum*, to the same sediments. Low density polyethylene devices (PEDs) and organisms were exposed in glass jars containing the sediment collected from different sampling stations of the lake for either 10 or 28 days. At the end of each test, the PEDs and mussels were analyzed for DDx concentrations. The concentrations obtained in the PEDs were then used to estimate the tissue concentrations in the corresponding exposed mussels. The results showed that the PED-deduced values were consistent with the measured levels for the 28-days tests, whereas the tissue concentrations predicted from passive samplers data were in some cases higher than the ones measured in the organism tissue after 10 days of exposure. This suggests that approach to equilibration of the sediment with a PED was faster than uptake by the benthic organism. These results show that PE samplers data may be quite effectively used to predict the concentration of a contaminant expected in the tissue of freshwater mussels, such as *U. pictorum*, thus allowing investigators to predict the bioavailabile fraction of organic contaminants in an easier and reliable way.

TU011

Perfluoroalkyl substances in aquatic environment - comparison of fish and passive sampling approaches

D. Cerveny, University of South Bohemia in Ceske Budejovice / Laboratory of Environmental Chemistry and Biochemistry; R. Grabic, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses Vodnany Czech Republic; G. Fedorova, University of South Bohemia in CB / Laboratory of Environmental Chemistry and Biochemistry; K. Grabicova, University of South Bohemia in CB / Faculty of Fisheries and Protection of Waters; J. Turek, University of South Bohemia in České Budějovice Faculty of Fisheries and Protection of Waters / Laboratory of Environmental Chemistry and Biochemistry; V. Kodes, Czech Hydrometeorological Institute / Section of water quality; O. Golovko, University of South Bohemia in CB / Lab of Environmental Chemistry Biochemistry; V. Zlabek, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters LECHB; T. Randak, University of South Bohemia in Ceske Budejovice/Faculty of Fisheries and Protection of Waters / Laboratory of Environmental Chemistry and Biochemistry

The concentrations of seven perfluoroalkyl substances (PFASs) were investigated in 36 European chub (*Squalius cephalus*) individuals from six localities in the Czech Republic. Chub muscle and liver tissue were analysed at all sampling sites. In addition, analyses of 16 target PFASs were performed in Polar Organic Chemical Integrative Samplers (POCISs) deployed in the water at the same sampling sites. We evaluated the possibility of using passive samplers as a standardized method for monitoring PFAS contamination in aquatic environments and the mutual relationships between determined concentrations. Only perfluorooctane sulphonate was above the LOQ in fish muscle samples and 52% of the analysed fish individuals exceeded the Environmental Quality Standard for water biota. Fish muscle concentration is also particularly important for risk assessment of fish consumers. The comparison of fish tissue results with published data showed the similarity of the Czech results with those found in Germany and France. However, fish liver analysis and the passive sampling approach resulted in different fish exposure scenarios. The total concentration of PFASs in fish liver tissue was strongly correlated with POCIS data, but pollutant patterns differed between these two matrices. The differences could be attributed to the metabolic activity of the living organism. In addition to providing a different view regarding the real PFAS cocktail to which the fish are exposed, POCISs fulfil the Three Rs strategy (replacement, reduction, and refinement) in animal testing.

Biological effects of emerging micro pollutants at realistic environmental concentrations (P)

TU012

A Preliminary Assessment of the Future Needs for Micropollutants in Turkey under Water Framework Directive Using Bibliometric Approach

m. Ozkaleli, Akdeniz University; K. Gedik, Akdeniz University / Dept Environmental Engineering; A. Erdem, Akdeniz University / Department of Environmental Engineering; P.B. Kurt Karakus, Bursa Technical University / Environmental Engineering Department; C. Moral, Akdeniz University / Department of Environmental Engineering; M. Asilturk, Akdeniz University / Dept of Materials Science and Engineering

Industrial chemicals, pesticides, drugs and drug residuals (pharmaceuticals), personal care products, steroid hormones and many other emerging pollutants are being considered under the term "micropollutants". Due to the diversity of micropollutants, the low concentrations, low treatment efficiency of micropollutants and their toxic effects, it is significant to monitor the micropollutants both in the environmental media and in the humans. To date, although discharge guidelines and standards do not exist for most micropollutants, some European Union (EU) countries have adopted regulations to set limit values. In Turkey, "Surface Water Quality Management Directive" adopted from EU-Water Framework Directive, targets to determine the environmental quality standards to regulate, detect and monitor the inorganic and organic micropollutants in surface, coastal and transitional waters, and in discharged wastewaters which may disrupt the water quality and ecological properties of those water bodies. For assessment of micropollutants, quantitative data are required. In order to evaluate the existing literature data and research trends in Turkey on micropollutants, a bibliometric analysis was performed for the period

of 1990 - 2015. Web of Science was used as the main database. The focus was set on selected micropollutants (policyclic aromatic hydrocarbons (PAH), polychlorinated biphenyl (PCB), and bisphenol A (BPA)) and environmental media (water, waste water, and sea water). The results of the study would provide an information on the currents status of the micropollutant species largely found in industrial, agricultural, natural or everyday life, would supply input for both national and international obligations, and would provide contribution to the development of our country-specific quality standards on many micropollutants in the near future. The authors would like to acknowledge the financial support from TUBITAK (Project No: 115Y309).

TU013
Ecotoxicological monitoring of photosystem II inhibitors in 5 small streams in Switzerland
M. Langer, Oekotoxzentrum Eawag-EPFL / Aquatic Ecotoxicology; B. Ganser, Swiss Centre for Applied Ecotoxicology Eawag-EPFL; M. Koster, Environmental Agency, Canton Thurgau / Gewaesserqualitaet; C. Kienle; E. Vermeirssen, Oekotoxzentrum Eawag-EPFL / Aquatic Ecotoxicology; I. Werner, Swiss Centre for Applied Ecotoxicology Eawag-EPFL
Small streams represent a major part of the Swiss river network, but so far information about pesticide pollution and pollution dynamics is limited. To investigate the situation in such small rivers, a special monitoring program (SPEZ) was conducted on five streams as part of the National Surface Water Quality Monitoring Network (NAWA) in spring and summer 2015. The aim of this project was to obtain knowledge about peak and baseline pesticide concentrations of over 250 different pesticides as well as their ecotoxicological effects. Selected sampling sites were located in areas intensively used for agriculture with different types of crops (grain, vegetables, vineyards and orchards). 12 h composite water samples were taken continuously from April to August 2015 using automated sampling devices. Samples were extracted using solid phase extraction and subsequently examined for 250 pesticides and metabolites using HPLC-HRMS. To complement the chemical analysis with ecotoxicological effect data, one week composite samples were analyzed for effects on algal photosynthesis and growth using the combined algae assay. This assay is especially sensitive for photosystem II-inhibiting substances. Toxic effects were expressed as diuron equivalent concentrations (DEQ) for photosystem II inhibition and as baseline toxic equivalent concentrations (baseline-TEQ) for growth inhibition. Photosynthesis inhibition was observed in 100% of the water samples, but at different levels. Calculated DEQs ranged between ca. 5 and 300 ng/L. Highest DEQs were found in June in areas with vineyards. In some cases high DEQs could be linked with rain events. During the sampling campaign longer periods without rain occurred whilst DEQs remained elevated. Consequently herbicides were introduced constantly to the streams even without rain events. The ecotoxicological effect data will be compared to use patterns and chemical concentrations measured.

TU014
Embryotoxic effects of reclaimed water in three different freshwater organisms: the Oryzias latipes fish, the Xenopus laevis amphibian and the Physa acuta snail.
P. Sanchez-Arguello, INIA - National Institute for Agricultural and Food Research and Technology / Environment; M. Gonzalez-Doncel, National Institute for Agricultural and Food Research and Technology / of the Environment; C. Fernández, National Institute for Agricultural and Food Research and Technology / Department of Environment Laboratory for Ecotoxicology; E.M. Beltrán, INIA - National Institute for Agricultural and Food Research and Technology / Environmental; P. Garcia, INIA National Institute for Agricultural and Food Research and Technology / Department of Environment; M. Pablos, INIA - National Institute for Agricultural and Food Research and Technology / Environment
Wastewater reuse is a promising strategy to supply water demands in both water scarcity and water pollution scenarios around the world. The challenge is to develop reliable technical and scientific tools to ensure safety uses of reclaimed water. Although many efforts have been focused on the improvement of technologies for wastewater treatments, the study of environmental impacts produced by wastewater reuse has received less attention. No drinkable reclaimed water uses include farming uses, such as agricultural irrigation and aquaculture. Reuse could also include landscape irrigation, building or replenishing wetlands that support wildlife, creating recreational lakes and several public uses as urban cleaning and park watering. Ecotoxicological studies with freshwater organisms are justified because reclaimed water contains complex mixtures of micro pollutants that can ultimately reach surface water. A comparative analysis of the response of early life stages from different species belonging to three taxa after exposure to reclaimed water is presented. Reclaimed water from wastewater treatment plants (WWTPs) that collect both municipal and municipal/industrial influents with different tertiary treatments (membrane bioreactor/ultraviolet, sand filtration/ultraviolet and lagoons) was sampled twice in one year. A comprehensive hazard assessment was performed by combining chemical analysis and ecotoxicity testing. Samples were analysed to look for 44 emerging contaminants including pharmaceuticals, endocrine disrupters and personal care products (PPCPs). Whole and diluted reclaimed water embriotoxicity was tested in samples and their fortifications obtained by adding a mixture of methylparaben (9 μg/L), PFOS (90 μg/L) and fluoxetine (400 μg/L). Three different exposure times were used: 10-day tests (modified OECD 210 method), 4-day tests (modified ASTM test, 2004) and 21-day tests (nonstandard method) for *Oryzias latipes*, *Xenopus laevis* and *Physa acuta*, respectively. Capability of methods used to ecotoxicity assessment of reclaimed water, species sensitivity and correlations between embryotoxicity and analytical measures are discussed. This work has been funded by the Spanish Ministry of Economy and Competiveness through CTM2013-44986-R and CTM2014-52388-R projects.

TU015
Effects of the cytotoxic drug cyclophosphamide exposure in the polychaete Nereis diversicolor
T.G. FONSECA, T.L. Rocha, N.C. Mestre, University of Algarve / CIMA; F.G. Ribeiro, C. Cardoso, M.J. Bebianno, University of Algarve / CIMA Centre for Marine and Environmental Research
Anticancer drugs are known to have potent cytotoxic, genotoxic, mutagenic, carcinogenic, endocrine and teratogenic effects in several organisms, since they were designed to disrupt or prevent cellular proliferation, usually by interfering in DNA synthesis. After patient's treatment, anticancer drugs and their metabolites are eliminated and directed in urban effluents to wastewater treatments plants where removal is not fully accomplished. Therefore, those pharmaceuticals may reach the surface and coastal waters arising concern regarding their fate and long-term effects in aquatic organisms. The sediment compartment in aquatic environments represents an important reservoir of toxic and relevant contaminants, becoming also a source of contamination for water and biota. Standardized ecotoxicological assays used in risk assessment have not been applied to anticancer drugs and even less to sediment quality assessment. Hence, there is a lack of knowledge about the bioavailability and possible adverse effects over the benthic biota of coastal waters regarding chronic exposure to low levels of such cytotoxic drugs. Cyclophosphamide (CP) is a worldwide applied cytotoxic drug with one of the most potent alkylating activity in the DNA, able to interact to double strands of prokaryotes and eukaryotes. In this sense, the present study applies a multibiomarker approach including behavior impairments (burrowing kinetic), biochemical biomarkers and genotoxicity, assessed by the Comet assay, in the sediment-dwelling polychaete *Nereis diversicolor* exposed to the alkylating agent CP in water-sediment systems, over 14 days. A range of concentrations that cover environmental relevant levels and worst-case scenarios were used (10 ng.L^{-1}; 100 ng.L^{-1}; 500 ng.L^{-1}, 1000 ng.L^{-1}). Results showed impairments of burrowing at the lowest concentration of the drug (i.e. 10 ng.L^{-1}) and at 500 ng.L^{-1}. Antioxidant enzymes activity and DNA damage were altered at higher concentrations.

TU016
Genotoxicity assessment of environmental concentration of veterinary antibiotics in fish (Prochilodus lineatus) using the micronucleus test and others nuclear abnormalities
R. Botelho, University of São Paulo / Ecotoxicology; J. Correia, UNESP Universidade Estadual Paulista Júlio de Mesquita Filho / Biology; C.A. Christofoletti, Fundacao Herminio Ometto / Environmental Mutagenesis; Y. Ansoar, UNESP Universidade Estadual Paulista Júlio de Mesquita Filho / Bi; L.A. Maranho, Center for Nuclear Energy in Agriculture/University of Sao Paulo; M. Santos, Fundacao Herminio Ometto; V. Tornisielo, CENA Center for Nuclear Energy in Agriculture
Veterinary antibiotics are one of the most used pharmaceuticals class in Brazilian fish farming for the treatment of bacterial diseases, and because of their intensive use, contamination of the aquatic environment may occur with effects to the native biota which lives where the fish farming is located. The goal of this study was to investigate the genotoxic effects of environmental concentration of oxytetracycline **and florfenicol** on juveniles of native fish from Brazil (*Prochilodus lineatus*) through the occurrence of micronucleus (MN) and other nuclear abnormalities (NA) after 96 hours exposure. Environmental concentration of oxytetracycline (8000 ng L-1) **and florfenicol (425 ng L-1)** were determined in surface water of a fish farm located at Ilha Solteira Reservoir (Santa Fé do Sul, São Paulo, Brazil) through Online-Solid-Phase Extraction coupled to Liquid Chromatography-Tandem Mass Spectrometry (Online-SPE-LC/MS-MS) in a previous study of our laboratory and exposed along with its double (16000 ng L-1 **and 850 ng L-1**) and its half (4000 ng L-1 **and 212.5 ng L-1**) on juveniles of *P. lineatus* during 96 hours in a static system. Although MN **was** observed after exposure to the concentrations 4000 and 8000 ng L-1 **of oxytetracycline** no statistical differences were observed when compared to the negative control ($p < 0.05$). **No MN was observed after exposure to flofenicol concentrations.** Four kinds of others NA were observed after exposure to oxytetracycline, which are: notched nuclei, blebbed nuclei, lobed nuclei, and binuclei **and five kinds after exposure to flofenicol with were: notched, blebbed, lobed, broken eggs and binuclei, but in both cases no statistical differences were observed** as well as for the sum of abnormalities when compared with the negative control ($p < 0.05$). **Environmental concentrations of oxytetracycline and flofenicol are not genotoxic to *P. lineatus* according to the MN test.**

TU017

Effects of exposure to carbamazepine and ibuprofen on the mussel Mytilus trossulus from the Baltic Sea

A. Pandolfi, University of Padova / Department of Biology; K.K. Lehtonen, Finnish Environment Institute / Marine Research Centre; P. Venier, University of Padova / Department of Biology; N. Perkola, Finnish Environment Institute / Laboratory Centre; R. Turja, Finnish Environment Institute / Marine Research Centre

Pharmaceuticals in aquatic ecosystems are an emerging issue in environmental research and the lack of knowledge in literature on their possible effects on non-target organisms is evident. In order to examine biological effects induced by the common drugs carbamazepine and ibuprofen in the mussel *Mytilus trossulus* from the Baltic Sea, a semi-static laboratory exposure experiment was conducted. Consistent with available data on the residual concentrations of the compounds recorded in the Baltic Sea the mussels were exposed for 7 days to nominal concentrations of 40 and 160 ng/L of carbamazepine and 20 and 80 ng/L of ibuprofen, and to their respective low and high concentration mixtures. Measured concentrations of the test compounds in water samples taken prior to each renewal of the test media at 48 hrs intervals were ca. 70-85% of the nominal ones. As consolidated biomarkers of oxidative stress the enzymatic activities of catalase (CAT), glutathione reductase (GR) and superoxide dismutase (SOD) as well as lipid peroxidation (LPO) were measured from the digestive gland tissue. The phase II detoxifying enzyme glutathione transferase (GST) was determined from the same tissue while the activity of acetylcholinesterase (AChE), an indicator of neurotoxic effects, was measured in the gill tissue. Apparent effects on the oxidative defence system with marked changes in CAT, GR and SOD activities could be recorded after exposure to the higher concentrations of carbamazepine and the mixture whereas no significant effects could be shown for ibuprofen. At the lower concentration range the mixture seemed to be more harmful than the individually introduced compounds, suggesting a possible additive or synergistic effect. No significant changes in the AChE activity and LPO could be detected.

TU018

Detoxification of azoxystrobin via biotransformation in Gammarus pulex is influenced by co-occurring substances

A. Rösch, J. Hollender, Eawag / Environmental Chemistry

Xenobiotics, such as pesticides and pharmaceuticals are distributed ubiquitously in the aquatic environment and their co-occurrence is often reported. Combined effects may arise that can influence the detoxification of substances via biotransformation and as a result toxic parent substances accumulate in the organism. In the present study the strobilurin fungicide azoxystrobin (AZ) was chosen to study the influence of co-occurring substances on its biotransformation in the aquatic invertebrate *Gammarus pulex (G. pulex)*. AZ exhibits a generally high toxicity towards aquatic organisms by inhibiting mitochondrial respiration. The effect of an enzyme inhibitor and an inducer on the oxidative drug metabolism was investigated using two binary mixtures. The mixtures were composed of AZ and prochloraz as well as of AZ and carbamazepine. The imidazole fungicide prochloraz is known to be a strong inhibitor of cytochrome P450 (CYP450) whereas the antiepileptic carbamazepine acts as inducer of CYP450. For the identification of biotransformation products (BTPs) and to investigate temporal trends *G. pulex* were exposed solely to AZ (40 μg L^{-1} & 80 μg L^{-1}) and to the two mixtures (concentration of inducer and inhibitor: similar molar concentration as used for AZ). By using high-resolution liquid chromatography tandem mass spectrometry combined with suspect and non-target screening approaches 17 BTPs of AZ were identified. The major biotransformation pathway was an ester hydrolysis to its acid combined with a hydrogenation. Further reactions detected include hydroxylations and diverse conjugation reactions with glucose, sulfate or the combination of both as well as with glutathione resulting in cysteine products. Temporal trends of the internal concentrations of the substrate AZ and its BTPs were compared between the sole exposure to AZ and the mixtures. Carbamazepine did not show any inducing effect in *G. pulex* i.e. similar internal concentrations for AZ and its BTPs were observed in the substrate control and in the mixture. For the mixture, where prochloraz was used as inhibitor, a strong inhibitory effect was observed. Maximum internal AZ concentrations were about twice as high in the mixture compared to the substrate control as a result of biotransformation inhibition also reflected in the estimated biotransformation rate constants. As a consequence, mortality of *G. pulex* increased in the mixture compared to the single exposure to AZ, indicating raised toxicity.

Dietary exposure to PVP/PEI coated Ag nanoparticles in adult mussels causes abnormal embryo development in offspring

N. Duroudier, A. Katsumiti, University of the Basque Country; M. Mikolaczyk, J. Schäfer, Université de Bordeaux; E. Bilbao, M.P. Cajaraville, University of the Basque Country

In the last years, silver nanoparticles (Ag NPs) have gained high commercial interest basically due to their antimicrobial properties. Applications for Ag NPs are increasing and thus, concerns about their potential input into aquatic ecosystems and their environmental hazards are also growing. Toxicity of Ag NPs to different freshwater and seawater organisms is being widely studied; however, there is a gap of knowledge on the potential toxic effects of Ag NPs ingested through the food web, especially at environmentally relevant concentrations. Further, most investigations are focused on understanding the effects of Ag NPs on exposed organisms, but potential effects on offspring have not been explored yet. The aim of this work was to assess the effects of dietary exposure to PVP/PEI coated Ag NPs on mussels immune status, reproductive success and offspring embryo development. Mussels *Mytilus galloprovincialis* were fed daily with microalgae *Isochrysis galbana* previously exposed for 24 hours to two different doses of PVP/PEI coated 5 nm Ag NPs: an environmentally relevant dose of 1 μg/L Ag NPs and a high dose of 10 μg/L Ag NPs. After 21 days of exposure, Ag bioaccumulation was determined in different tissues and immunotoxicity was assessed in hemocytes. In addition, mussels were induced to spawn and sperm motility, spawning success, fertilization success and development of abnormal larvae were checked. Mussels fed with microalgae exposed to both doses of Ag NPs significantly accumulated Ag after 21 days, showing a successful transfer of incorporated Ag NPs from microalgae to mussels. Phagocytic activity of hemocytes was slightly reduced, contrary to the immunostimulatory effect reported earlier for Ag NPs and other NPs. No significant differences were observed for sperm motility, number of spawned eggs and fertilization success. However, a significantly higher percentage of abnormal embryos were observed after parental exposure to both doses, even for the dose close to environmentally relevant concentrations. Future studies are needed to address mechanisms and consequences of NP exposure for the early life stages of mussels and other organisms. Funded by: Spanish Ministry of Economy and Competitiveness (NanoSilverOmics MAT2012-39372), Basque Government (SAIOTEK S-PE13UN142 and Consolidated Research Group GIC IT810-13), UPV/EHU (UFI11/37 and PhD fellowship to N.D.) and French Ministry of Higher Education and Research (PhD fellowship to M.M.)

Including different biological and space complexity scales in hazard assessment : a case study with diclofenac sodium PNEC derivation

A. JAMES-CASAS, INERIS / Toxicological Ecotoxicological Assessment of chemical Substances ETES; S. JOACHIM, INERIS / CIVS; R. Beaudouin, INERIS / Models for Ecotoxicology and Toxicology METO; A. Bado-Nilles, INERIS; G. Daniele, Institut des Sciences Analytiques / TRACES Team; E. Vulliet, CNRS / TRACES Team; P. Baudoin, O. Palluel, C. TURIES, INERIS / INERIS UMRI SEBIO ECOT; A. Geffard, Université de Reims Champagne Ardenne; J. Porcher, INERIS / INERIS UMRI SEBIO ECOT; S. ANDRES, INERIS / Toxicological Ecotoxicological Assessment of chemical Substances

Use of parent and metabolized drugs and their subsequent indirect emissions in aquatic ecosystems are a source of contamination of these and implies improvement of the scientific knowledge on their likely ecotoxicological impacts and of the tools to assess them. This is the goal of the DOREMIPHARM project, which aims at providing robust ecotoxicological data for drugs judged as of concern for their potential ecotoxicological risk as regards aquatic ecosystems. More widely, this research project also aims at developing robust hazard assessment tools for these pharmaceutical substances. The project involves different partners and their corresponding skills in order to implement a large number of tools allowing the testing of different conventional and non conventional endpoints (from a regulatory viewpoint). The project tasks allow data production for the implementation of an environmental risk assessment of the pharmaceuticals. The aim of this poster is to give an overview of the possible levels of assessment that may be taken on board for environmental hazard assessment of pharmaceuticals, focusing on the work done on diclofenac sodium. In fact, while traditional and regulatory Predicted No Effect Concentrations (PNECs) are usually based on the so-called “conventional” endpoints such as mortality and sublethal endpoints (e.g. growth, reproduction, development), it is here proposed to compare how the inclusion of less conventional endpoints may drive differently the hazard assessment. These endpoints depict different complexity scales as regards space (laboratory *versus* mesocosm data) and as regards biological organisation (community, population, individuals, cellular, biochemical). Applying this methodology, the so-called early-warning endpoints are compared to effects observed at community or populational level. Then, different PNECs are derived and presented : “traditional PNECs” covers conventional endpoints for at least three trophic levels (algae, crustaceans and fish), while “non conventional PNECs” may take account of the mesocosm study data obtained during the project but also of biomarkers response (e.g. biomarkers of effects such as immunotoxicological or respiratory burst effects).

TU021

How to investigate the impact of a multitude of micropollutants on the freshwater community? - Conceptual approach to address community level effects

M. Hammers-Wirtz, S. Classen, Research Institute gaiac

A multitude of micropollutants is regularly detected in freshwater ecosystems over the last years and there is an increasing concern that micropollutants – even if they were present in very low concentrations - may contribute to the losses of biodiversity observed in freshwater communities. In 2015 in North-Rhine

Westfalia (Germany) more than 90% of the freshwater ecosystems failed reaching the good ecological status, a target set by the EU's Water Framework Directive (WFD). Many micropollutants like pharmaceuticals, contrast agents, industrial chemicals, personal care products and some pesticides and biocides enter the aquatic environment by wastewater discharge, because these micropollutants are not or only partially eliminated by conventional wastewater treatment plants. Hence, wastewater is considered as one of the major sources of micropollutants in the aquatic environment. Bioassays conducted in the lab with representative species help to investigate the potential effects of complex mixtures of micropollutants on single species. In fact short-term effects of wastewater treatment effluents on different test organisms could be demonstrated by a set of bioassays in several research projects. Additionally, some bioassays conducted as by-pass test systems showed chronic effects of micropollutants on single species, too. Furthermore, monitoring results of freshwater communities in receiving water bodies before and after improvement of a wastewater treatment plant indicated that the quality of the introduced wastewater affects the macroinvertebrate communities. However, monitoring freshwater communities always includes many other influencing factors (e.g. temperature, velocity, habitat structure) which makes it impossible to analyse the effects of micropollutants alone. Therefore, it is still unclear how strong the multitude of micropollutants discharged by wastewater treatment plants will actually affect freshwater communities. We will present a conceptual approach of artificial stream mesocosms allowing to evaluate the impact of micropollutants alone without other influencing factors present in natural flowing water bodies. This approach allows us to investigate whether advanced wastewater treatment technologies like ozonation and activated carbon filtration will potentially improve the ecological status of macroinvertebrate communities.

TU022

Biological effects of anthropogenic pollutants present in pond receiving treated municipal sewage water

P.T. Giang, University of South Bohemia / Faculty of Fisheries and Protection of Waters; T. Randak, University of South Bohemia in Ceske Budejovice/Faculty of Fisheries and Protection of Waters / Laboratory of Environmental Chemistry and Biochemistry; R. Grabic, 2University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters; G. Fedorova, University of South Bohemia in CB / Laboratory of Environmental Chemistry and Biochemistry; K. Grabicova, University of South Bohemia in CB / Faculty of Fisheries and Protection of Waters; O. Koba, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters; O. Golovko, University of South Bohemia in CB / Lab of Environmental Chemistry   Biochemistry; V. Burkina, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses Vodnany Czech Republic; S. Sakalli, University of South Bohemia Ceske Budejovice / Faculty of Fisheries and Protection of Waters; V. Zlabek, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters LECHB

In this study, we aim to assess biological effects of mixture of emerging pollutants, present in recipients of treated sewage water in common carp (*Cyprinus carpio*). Four samplings (after 0, 30, 90, 180 days) have been done in April-November, 2015. Cezarka pond, a biological pond which receives water from sewage treatment plant in Vodnany, Czech Republic (approx. 7000 inhabitants) has been studied. Anthropogenic pollutions such as persistent organic pollutants, pharmaceuticals and personal care products have been detected and identified in water and sediments. Fish were exposed in real condition at size of 17.05 ± 1.25 cm total length and 65.80 ± 15.12 g total weight. The effect of complex pollution on fish was identified. The oxidative stress and antioxidant enzymes activities were measured in liver, gill, muscle, and intestine fish tissues. At 180 days of experiment the weight of exposed fish was remarkably higher when compare to control group. Nutrient load in biological pond resulted in high abundance of plankton and macrophytes compared to control. It suggests that the growth was not affected by identified pollutants, while the difference may be due to amount of natural food available in Cezarka pond. However to understand the full picture of effects of anthropogenic pollution, it is necessary to consider other information regarding chemical, biochemical and reproductive endpoints. *Keywords:STP effluents,mixture effects, fish, biological pond* Acknowledgement: This work was financially supported by the Ministry of Education, Youth and Sports of the Czech Republic – projects "CENAKVA" (No. CZ.1.05/2.1.00/01.0024) and "CENAKVA II" (No. LO1205 under the NPU I program), by the Grant Agency of the University of South Bohemia in Ceske Budejovice (No. 012/2016/Z), by the Czech Science Foundation (No. 15-04258S).

Effects of environmental realistic concentrations of carbamazepine in a freshwater model ecosystem

S. JOACHIM, INERIS / CIVS; R. Beaudouin, INERIS / Models for Ecotoxicology and Toxicology METO; E. Vulliet, CNRS / TRACES Team; A. Bado-Nilles, INERIS; G. Daniele, Institut des Sciences Analytiques / TRACES Team; P. Baudoin, O. Palluel, C. TURIES, INERIS / INERIS UMRI   SEBIO ECOT; A. JAMES-CASAS, INERIS / Toxicological   Ecotoxicological Assessment of chemical Substances ETES; S. ANDRES, INERIS / Toxicological Ecotoxicological Assessment of chemical Substances; A. Péry, INRAAgroParisTech; J. Porcher, INERIS / INERIS UMRI   SEBIO ECOT

Pharmaceuticals are widely used in human and veterinary health care products. Their occurrence in the aquatic environment is nowadays a well established issue and has become a matter of both scientific and public concern. As these substances are biologically active and might be persistent, toxic effects on organisms are suspected at low concentrations and have been demonstrated mainly for steroidal hormones. Carbamazepine is a common drug used for the treatment of epilepsy, which is frequently found in European freshwater ecosystems. As chronic ecotoxicity data as well as information on the current distribution patterns in environmental compartments are scarce, an integrated hazard assessment strategy was proposed based on low tier (standardized tests, biomarkers studies) and high tier studies (lotic mesocosms). The results of the lotic mesocosm experiment are described in this communication. The study was carried out, in twelve 20 meter long channels, under continuous, environmentally realistic concentrations of carbamazepine (0.05, 0.5 and 5 μg L^{-1} in triplicats). The mesocosms were set up with artificial sediments, macrophytes, periphyton, benthic and pelagic invertebrates, decomposers and one fish species (*Gasterosteus aculeatus)*. After three months of ecosystem stabilization, treatment lasted 6 months. Periphyton biomass, macrophyte biovolume, zooplankton and invertebrate abundance and diversity, fish individual physiological responses along with population dynamics were the measured biological endpoints. Carbamazepine concentration in water was monitored each month by chemical analysis. In order to account for the observed effects, degradation products and major metabolites were also measured in the sediment, watercress and fish. Major effects on water quality parameters, macrophytes and fish were observed at the highest tested concentration. Moreover, a quite important physiological destabilization of fish was shown at 0.5 and 5 μg L^{-1}.All these impacts could be caused by both the parent substance and the degradation products and metabolites. Retroactive effects seem to drive and structure the responses of the other populations and communities. A conceptual model presenting the overall response at the highest tested concentration is proposed.

Ecotoxicology and risk assessment of nanomaterials - Grouping and read-across (P)

TU024

In silico models for nanoparticles: are we ready for regulatory application?

E. Papa, Department of Theoretical and Applied Sciences; P. Gramatica, University of Insubria / DiSTA

The use of alternatives to animal testing such as *in silico* models based on Quantitative Structure-Activity Relationships, grouping and read across methods to reduce experimental costs and speed up risk assessment procedures, is a main innovation introduced officially by the REACH regulation in 2007. However, the need for identification of harmonized criteria for the evaluation of the reliability and applicability of QSAR models represented a real priority since the white paper on REACH, published in 2001. The approval and publication in 2004 of the OECD Principles for the regulatory use of QSAR, and the following OECD (2007) and ECHA guidelines (2008), represented milestones in the process of application of *in silico* strategies for the modelling and the prediction of properties and activities for traditional and industrial chemicals. These documents are based on experiences gained during decades of development, validation and application of QSARs to thousands of organic substances. Currently, the large development of nanotechnologies and the uncertainties related to possible effects and risks posed by these new materials to humans and the environment, have increased the interest of scientist and regulators in computational nanotoxicology, which is expected to provide key elements in the determination of missing data by *in silico* predictions. However, traditional schemes for models development and validation such as those described in the aforementioned OECD Principles, find difficult application to nanomaterials due to lacking input data, consequent limitations in the quality and dimension of the modelled datasets, and to a variety of factors, which strongly influence the behavior of nanoparticles. In this poster we analyze and present different issues related to the development and validation of computational QSAR-type models generated for nanoparticles. The analysis is performed on real datasets and models, following the OECD Principles for the regulatory use of QSARs and highlighting criticalities associated to the application of these five principles. The aim of this poster is to generate discussion and reflection on a sensitive topic such as the possible regulatory validity and use of predictions generated by *in silico* models developed for nanoparticles.

TU025

Are we ready for read-across approaches to support regulatory decision-making of nanomaterials?

Y. Sultan; T. Francis, B. Fisher, Environment Canada

Regulatory jurisdictions continue to assess and manage potential risks associated with manufactured nanomaterials. In addition to assessing new nanomaterials, Canada has recently published an approach to assess and manage existing nanomaterials. To support domestic and international needs, approaches are needed to leverage existing information in risk assessments. These read-across frameworks (or approaches), which allow users to address gaps in data-poor substances with information from other nanomaterials, have become a priority for most jurisdictions. This need is driven by a combination of: short timelines to make regulatory decisions, conducting assessments which span different physical forms of nanomaterials, and the move towards reduced animal testing. However, many of the published read-across frameworks for nanomaterials are underpinned by principles of conventional chemicals. As such, these frameworks cannot be used for nanomaterials without first identifying the specific nano-properties of interest and second by conducting case studies to validate these approaches for nanomaterials. This presentation will provide an update on Canada's domestic regulatory program and activities under the Organization for Economic Cooperation and Development (OECD) Working Party on Manufactured Nanomaterials (WPMN) on the use of read-across in support of regulatory decision making. The intention of this presentation is to inform on the ongoing needs associated with read-across frameworks for nanomaterials while highlighting gaps which need to be addressed to improve the uptake of these approaches for regulatory decision-making in the future.

TU026

Reflect laboratory results the fate and effect of nanomaterials in the environment and represent appropriate data for grouping?

K. Schlich, M. Kraas, Fraunhofer IME   Institute for Molecular Biology and Applied Ecology; K. Hund-Rinke, Fraunhofer IME

The grouping of nanomaterials (NM) is based primarily on standardized, ecotoxicological laboratory experiments. However, whether data of laboratory experiments are comparable with data from field experiments has not been determined so far. The comparability of both is the basis for any grouping effort. The main goal of this study was to show if the data on fate and effects of a silver NM (AgNM: NM-300K) and a CeO_2 NM (CeO_2 NM: NM-212) from the OECD Sponsorship Programme in field lysimeters is comparable with laboratory results. Experiments with AgNM started in May 2014 and with CeO_2 NM in May 2015. Both will end in 2017. Eight field lysimeters (0.9 m x 0.9 m x 0.9 m) are used and various crops are planted. The NM were applied on the field lysimeters via sewage sludge (Ag, CeO_2) and simulated rain (CeO_2). For the application of NM via sewage sludge, sludge was removed from a municipal sewage treatment plant and mixed for 24 h with the NM. The sludge was dewatered and introduced into soil in accordance with the German Sewage Sludge Ordinance (5t per ha in 3 years, applied at once). For the application via simulated rain periodically CeO_2 NM dispersion was prepared over four weeks, which was applied in 2.5 liters of deionized water on the soil surface. The top 20 cm of soil were circulated to simulate the agricultural use of a plow. After the NM had been incorporated into the soil, wheat was sown at first and subsequently canola and barley. For the AgNM lysimeter, via sludge concentrations of 1.8 and 7.0 mg/kg dry soil were measured. On the CeO_2 lysimeters with the sludge application concentrations of 9 and 40 mg per kg soil were reached and applied as simulated rain 9 mg/kg soil were measured. Directly after the application and at the end of each growing period, soil samples were taken and the influence of the NM on the soil microflora was determined using the potential ammonium oxidation (ISO 15685:2012). In addition the influence on the growth of crops and the fate of the NM in soil and the plants was determined. The first results show that AgNM remain in the top 20 cm of the soil and can be found in low concentrations in the roots of wheat. The soil microflora is inhibited by the AgNM at the highest test concentration. There is a good comparability of the laboratory and the field experiments during the first 140 days. First results regarding the toxicity show, that the CeO_2 NM did not affect the soil microflora at test start (lab and field tests).

TU027

Grouping of nanomaterial and hazard assessment: requirements for additional criteria to assess the quality of studies

l. geoffroy, S. ANDRES, INERIS / Toxicological   Ecotoxicological Assessment of chemical Substances

In several occasions, scientists can predict the effects of nanomaterials that are in the same category. When possible, grouping is done to simplify analysis, decisions, and to help to select relevant assays. Fate categories could possibly be used to dictate the need for hazard tests or hazard profile to dictate environmental behavior. Nevertheless, to determine hazard in a regulatory framework, assays have to be conducted under defined guidelines and studies are assessed under a score system (i.e. the Klimisch score) to determine if information quoted are sufficient and incertitude acceptable. With this respect, as work is currently done to improve and adapt existing guidelines for nanomaterials, the need for additional quality criteria is emerging. In particular, nanomaterial identification is crucial in hazard assessment and grouping. A list of 10 parameters considered as necessary to identify nanomaterials. The aim of this study is a tentative to identify parameters needed for nanomaterials to validate a study, in order to improve the score system with adaptation for nanomaterials. Data are collected from literature for different nanomaterial tested (TiO2 and Ce for example) and analyzed. For each study, parameters assigned and results of test toxicity are reported. Parameters mainly linked to toxicity are tested using multivariate statistical analysis (PCA for example), which can help in identifying crucial parameters to estimate the quality of the study. Based on these results, a prioritization of additional parameter to be included when assessing the quality of a study using nanomaterials is proposed.

Ecotoxicological impacts of engineered nanoparticles in aquatic model systems

M. Lukas, Federal Environment Agency (UBA) / Ecotoxicological Laboratory; C. Polleichtner, German Environment Agency (UBA) / Ecotoxicological Laboratory; C. Kussatz, Federal Environmental Agency UBA / Ecotoxicological Laboratory

The ecotoxicological effects of engineered nanoparticles (ENPs) are mostly unknown. However, their industrial use is continuously rising. Particularly, studies on prevalent and commercial relevant ENPs with innovative functionalized variations (e.g., coating or doping) are lacking. Therefore, the German Federal Ministry of Education and Research (BMBF) has launched the programme “NanoNature“ in 2008. This programme supports and promotes research projects aiming to understand the impacts of ENPs on the environment in general and on organisms in particular. As a part of NanoNature “DENANA” (“Design criteria for sustainable nanomaterials”) is a joint research project of 10 academic, industrial and regulatory partners that currently tries to conciliate the conflict of immediate marketing of innovative ENP-products and the precautionary principle regarding the potential environmental risks. Within this framework the Ecotoxicological Laboratory of the German Federal Environment Agency (UBA) is investigating the biological effects of differently functionalized ENPs (silicon dioxide, cerium dioxide and silver nanoparticles) on various aquatic organisms. Main objective is to provide a solid long-term data set on ENPs in aquatic ecosystems which can be used for hazard estimation and risk assessment in chemicals policy. Therefore, ecotoxicological tests with several species representing different trophic levels in aquatic ecosystems, ranging from green algae (*Desmodesmus subspicatus*) and higher macrophytes (*Lemna minor*) to invertebrates (*Daphnia magna*) and vertebrates (*Danio rerio*) started. Moreover, test designs for multigenerational studies with daphnids were developed to estimate the long-term impact of ENPs. Additionally, several analytical methods such as dynamic light scattering (DLS) to describe the particle size distribution of ENPs, the determination of zeta potentials and chemical analysis of ENPs in aqueous solutions began. Results will show if the currently used classification of the investigated ENPs as less toxic (e.g., SiO_2 nanoparticles) holds also for functionalized variations and will offer criteria for designing sustainable nanomaterials. Furthermore, experiments will add up of long-term data on the environmental exposure which provides a basis for regulatory concerns.

TU029

SOS-Nano: the Structure-Oxidative Stress relationship of metal oxide nanoparticles in the aquatic environment

S. Noventa, University of Exeter / Biosciences College of Life and Environmental Sciences; T.S. Galloway, University of Exeter / Biosciences Department

The Marie Sklodowska-Curie Action funded SOS-Nano project addresses one of the pressing issues of econanotoxicology: to investigate how the structural properties of nanoparticles (NPs) can be used to predict their potential toxicity in aquatic environments, the final sink of released NPs. The project is using the oyster (*Crassostrea gigas*) as a model organism to investigate the toxicity of a range of metaloxide (MOx) NPs exhibiting different physico-chemical characteristics. The experimental plan of SOS-Nano is designed to highlight the relationships between the physico-chemical proprieties of the model NPs (Mn_2O_3, CeO_2 and ZnO) and the toxic activity under the influence of natural water properties, and to rank their toxic potential through a multi-tier system combining genomics and functional measurements. The NOx NPs exposure settlements mimic different conditions of salinity and natural organic matter concentration, expected to influence NPs aggregation-stability-reactivity in marine environments; the characterization of the behaviour of model-NPs in the exposure settlements is complemented by the assessment of bandgap energies, dissolution and NP biological fate within target-organisms. The induction of oxidative stress in the oyster embryos is being determined in accordance with the *Hierarchical Oxidative Stress Paradigm*, which describes the progressive induction of cellular responses classified as antioxidant defence, pro-inflammatory effects and cytotoxicity. The toxic responses are being ranked through a multi-tier system combining genomics and functional measurements. The poster will present preliminary data on the physico-chemical proprieties of our chosen model NPs under different exposure scenarios and the extent to which they induce oxidative stress in the test organisms. This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 655134.

Categorisation approaches and grouping for read-across of manufactured nanomaterials

L. Lamon, Euro Mediterranean Centre for Climate Change / Institute for Health and Consumer Protection IHCP; D. Asturiol, K. Aschberger, European Commission   Joint Research Centre / Institute for Health and Consumer Protection IHCP; A. Worth, Joint Research Centre / Institute for Health and

Consumer Protection IHCP
The Registration, Evaluation, Authorisation and Restriction of Chemicals regulation (REACH, EC No 1907/2006) is safeguarding the safety of manufactured nanomaterials (MNs) while at the same time encouraging the reduction of in vivo tests promoting in vitro and in silico approaches. Annex XI of the regulation provides for the application of grouping and read-across when testing is not considered scientifically necessary and categories can be properly defined in terms of similarity. The need to apply grouping approaches to MNs testing has been highlighted by several guidance documents from regulatory bodies given that assessing risks posed by all MNs on a case-by-case basis is challenging in terms of financial resources, ethical considerations and time demand. However, a reference guidance framework for MN read-across is not available yet. The ECHA Group Assessing Already Registered Nanomaterials (GAARN) has identified key issues and concepts to be explored in MNs grouping and read-across, including the need to consider properties beyond chemical composition (e.g. aspect ratio, particle size, shape, solubility, etc.), the identification of similarity rules in support of the application of REACH Annex XI to MNs, the relevance of toxicokinetic studies in grouping and read-across and in extrapolation from in vitro to in vivo tests. We have analysed the published literature on categorisation schemes and read-across for MNs. The proposed categorisation approaches cover a variety of assessment goals, including priority setting of MNs for further evaluation (including ranking based on level of concern) and guiding the choice of relevant endpoints and methods. In this paper we report what is available in the literature and identify research gaps, with a special attention to the provisions of REACH Annex XI in order to support further activities in this area.

TU031
Agglomeration behaviour of nanomaterials in environmentally relevant aquatic media - towards a nano-specific OECD test guideline
P.A. Kozin, Vienna University / Environmental Geosciences; F. Von der Kammer, Vienna University / Department of Environmental Geosciences; T. Hofmann, University of Vienna / Department of Environmental Geosciences
Agglomeration behaviour is an important parameter affecting the environmental behaviour of nanomaterials. It depends on physicochemical characteristics of the dispersion media and agglomerating nanomaterial, its concentration and concentration of other substances in the dispersion. This study suggests experimental method (proposed as an OECD test guideline) and provides international regulatory guidance for testing nanomaterial agglomeration behaviour in environmentally relevant aquatic media. Proposed method determines nanomaterial agglomeration behaviour by analysing remaining particle concentration in the top 0.5 cm volume of the dispersion over a 6 hour time-period (0-6 hours). For a fully stable dispersion, this concentration did not change over time, while agglomeration and settling of nanomaterial gradually reduced the concentration of particles in this volume of the sample. TiO_2 (NM105) nanomaterial was chosen to study agglomeration behaviour in dispersions containing 0, 1, and 10 mM $Ca(NO_3)_2$ electrolyte and dissolved NOM (SRNOM, 30ppm). Agglomeration behaviour was studied in the presence and absence of CO_2 and at natural and established (5, 7, 8.5) pH. Resutls showed that dispersions of TiO_2 (NM105) were unstable proportionally to the amount of added electrolyte. Addition of NOM had a potential stabilizing effect on the system containing 1 mM $Ca(NO_3)_2$. Absence of CO_2 in the atmosphere above the analysed TiO_2 (NM105) dispersions did not improve or deteriorate the stability of electrolyte or electrolyte-DOM containing dispresions. Dispersions of TiO_2 (NM105) were unstable at pH values 5 and 7, closest to the PZC of TiO_2 (6.5). Dispersions at pH=8.5 revealed stability comapred to that of the systems analysed at natural pH. The decision tree, developed as a result of this study, provides the experimental routine to test the agglomeration behaviour of nanomaterials in aquatic media. Decision tree is designed to address the issue of nanomaterial agglomeration behaviour in such way that would require the minimal time- and cost- spending, through the combination of "dispersibility" and "dispersion stability" test approaches. Thus proposed experimental method allows not only observation of nanomaterial agglomeration behaviour, but also understanding of reasons and factors influencing this process.

TU032
Grouping of nanomaterials regarding aquatic ecotoxicity - hypotheses for selected NMs and experimental proof
K. Hund-Rinke, Fraunhofer IME; T.A. Kuhlbusch, Institute of Energy and Environmental Technology e.V. - IUTA / Air Quality Sustainable Nanotechnology; D. Kühnel, Helmholtz-Centre for Environmental Research / Bioanalytical Ecotoxicology; C. Nickel, Institute of Energy and Envionmental Technology e.V. - IUTA / Air Quality Sustainable Nanotechnology; K. Schlich, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology
Due to the large variability of nanomaterials (NMs) the testing of every modification would require a tremendous amount of work and costs. Therefore, grouping of NMs is intended, limiting the number of comprehensively tested NM to a few considered as representative for a group. The NMs of each group have comparable characteristics with respect to the intended protection objective (e.g. ecotoxicity). Aims of this ongoing project are first the correlation of data of physico-chemical (PC) properties of selected NMs (Ag, TiO_2, ZnO, CeO_2) with ecotoxicological data and second the identification of suitable parameters as basis for grouping. Based on a literature review, for each of the selected NM-types parameters were identified which are expected to be relevant for ecotoxicological effects. For every NM-type 2 – 4 uncoated sub-NMs were selected (in total 12 NMs). The selected NMs were tested with algae (OECD 201), daphnids (OECD 202) and fish embryos (OECD 236), considering the modifications proposed for the testing of NMs. The NMs were characterized in Milli-Q-water and in the respective test media (OECD medium for algae, ADAM for daphnids, ISO water for fish embryos). Parameters such as surface size, crystalline structure, morphology, primary size, particle size distribution in dispersion, zeta-potential, dissolution, reactivity (CPH, ROS) were addressed. NM characteristics in water can differ significantly from those determined in test media. For example, for the spherical Ag NM (Æ 15 nm) the ion concentration after 72 h was in the range of 437 – 490 mg/L in water and the various test media. For a silver rod with a length of 3797 nm, the dissolution differed between 230 mg/L in water and 0.3 – 1.3 mg/L in the test media. The dissolution of a second silver rod (length: 2423 nm) in water and the test media differed by factor 10 (0.101 mg/L and 0.012 – 0.038 mg/L). Therefore, for a correlation of PC parameters with ecotox data only values determined in the test media should be used. For Ag, dissolution was expected to be the most relevant parameter. However, correlation between EC50 values and dissolution is weak. Differences in toxicity of the NMs were significantly lower than expected based on the dissolution. Daphnids proved to be the most sensitive test organisms although dissolution in the test medium ranked between the dissolution in the algae and fish medium. Additional PC-parameters which still have to be defined have to be considered for grouping.

TU033
A systematic investigation of the ENMs toxicity to freshwater organism: the search of the key physiochemical parameter
B. Salieri, EMPA / C.I.R.S.A; A. Pasteris, University of Bologna; R. Hischier, EMPA / Technology and Society Lab
Engineered nanomaterials (ENMs) are applied in more and more different products and areas. Therefore, concerns regarding the potential human and environmental impacts of ENMs have risen. However so far it is unclear, how the novel properties of ENM result in an increase of their toxicological potential compared to classical (microscale) substances. Then despite the increasing investigation to assess the potential risks of these emerging contaminants, a full characterization of the potential human and environmental impacts of these materials is still missing. As well, the physicochemical parameter which determines the toxic effect is still far to be clearly declared. A bibliographic survey concerning toxicity studies on the freshwater organisms representative for the trophic levels of Algae, Crustaceans, and Fish respectively, have been conducted for MWCNT, SWCNT, and Fullerene. This bibliographic survey resulted in ecotoxicity data-set on CNMs – organized according to: (1) Type of CNT; (2)Trophic level; (3) Physicochemical properties Length (nm), Primary Diameter (nm), surface area (m2/g), functionalization; (4) Use and type of dispersant; (5) System-dependent properties; (6) Ecotoxicity tests. All collected data has been analysed by applying the statistical tools as analysis of variance (ANOVA), correlation analysis and polynomial regression analysis. Thus, the correlation between physicochemical properties of CNMs and their toxic value as EC50s is here determined using *different statistical approaches*. Among the group of MWCNT, SWCNT, and fullerene respectively, different pyshicochemical properties have been found to have a significant effect on toxicity by the ANOVA analysis. The matrix of correlation coefficients approach shows, e.g. for SWCNT-crustaceans, that the exposure time and the length have a positive and strong correlation with the EC50 values whereas a negative and weak relationship with EC50 values. The lack of data in term of characterization of the ENM both in the media or in the commercial available form were the main limitations to the investigation. On our knowledge the approach here proposed is for its first time proposed and it might be useful as a first basic investigation for the identification of key parameters of relevance for the assessment of ENMs.

Ecotoxicology and risk assessment of nanomaterials - Interactions at nano-bio interface (P)

TU034
Potential on the application of multi-luminescent bacteria for ecotoxicological screening of nanomaterials
S. Baik, KIST Europe / Environmental Safety Group; Y. Jung, KIST-Europe; Y. Kim, KIST-Europe / Environmental Safety Group
A number of studies has investigated toxicological effects of nanomaterials with various methods and addressed the potential toxicity on different systems. Among the groups of nanomaterials, silver nanoparticles (AgNPs) are of concern for their potential biocidal effects of both ionized and particulated forms. In this study, four different surface-coated AgNPs, coating of citrate (Cit-), tannic acid (Tan-), poethylene glycol (PEG-), and branched polyethyleneimine (BPEI-), were selected to investigate toxicological effects. A luminous microbial array for toxicity risk assessment (LumiMARA) using multi-species of luminescent

bacteria was used to evaluate for those AgNPs. To date, various acute toxicity bioassays using bacteria for toxicity screening have widely been applied to understand the ecotoxicological impacts of pollutants on aquatic organisms due to their advantages such as simplicity, rapidity, and cost-efficiency. Using single-strain of bacteria, however, may have some limitations of the various sensitivity ranges compared to using multi-species of bacteria. To overcome this limitation, application of multi-species of luminescent bacteria as the potential ecotoxicological screening tool for surface-coated AgNPs was investigated. Different time-dependent inhibition rates for all tested AgNPs exposed to each luminescent bacteria were achieved and used for dose-response curves to calculate the values of the 50% effective concentration (EC_{50}). The values of EC_{50} for BPEI-AgNPs (1.57 to 5.19 mg/L) were lower than those for the other surface-coated AgNPs (i.e., Cit-AgNPs, Tan-AgNPs, and PEG-AgNPs). It appears that the toxicity of AgNPs could be activated by the interaction of positively charged AgNPs with the negatively charged bacterial cell wall. Effects of the sole coating materials were also investigated and achieved similar toxicological trends to surface-coated AgNPs, and consequently, coating materials may induce toxic effects of surface-coated AgNPs on the exposed lumenescent bacteria. The short exposure time of LumiMARA, 15 min, would be drawback for the applicability as the toxicological assessment of nanoparticles, which may have slow toxicity reaction. However, the advantages in simplicity, rapidity, cost-efficiency, and reproducibility of this bioassay may lead to have a potential applicability as an acute toxicity pre-screening tool for the environmental sample containing nanoparticles.

TU035

The effect of surface oxidation on the dispersion and biotoxicity of carbon nanotubes

L. Zhang, Zhejiang University / Environmental Science; R. Deng, D. Lin, Zhejiang University / Department of Environmental Science

Carbon nanotubes (CNTs) are employed in a variety of applications due to their unique and extraordinary properties, causing increased discharge of CNTs into aquatic environments and thereby threatening aquatic organisms. However, the severe homoaggregation of carbon nanotubes (CNTs) due to their high hydrophobicity strongly limits their efficient utilization. Surface oxidation is considered to be an effective way to improve the dispersity of CNTs. In this study, we treated mutiwalled CNTs (MWCNTs) with concentrated H_2SO_4/HNO_3 to prepare surface oxidized MWCNTs (o-MWCNTs), investigated changes in surface properties of the MWCNTs after oxidation, and evaluated the effect of oxidation on the suspension stability and biotoxicity of the MWCNTs. The contents of oxygen and oxygen-containing groups including carboxyl, hydroxyl, and ester groups of the MWCNTs increased and the point of zero charge of the MWCNTs decreased with increasing oxidation time. The specific surface area of the MWCNTs increased as oxidation time increased due to the disclosed tube ends and the untied CNT bundles. The concentration of stabilized MWCNT suspension increased with ultrasonication time, and the o-MWCNTs had much higher stability than the pristine MWCNTs. Changes in surface property and colloid behavior of the MWCNTs by the oxidiation substantially altered their biotoxicity. The o-MWCNTs exhibited significantly higher toxicity toward the algae (*Chlorella Pyrenoidosa*) and bacteria (*Escherichia Coli*) than the pristine MWCNTs, and higher toxicity was observed for the o-MWCNTs with higher degree of oxidation. **Keywords:** Carbon nanotubes; oxidation; dispersion; biotoxicity

TU036

Effects of cationic polystyrene nanoparticles in the hemocytes of the marine bivalve Mytilus: role of soluble hemolymph factors

C. Ciacci, University of Urbino; R. Fabbri, T. Balbi, University of Genova / DISTAV; K. Cortese, university of genoa; E. Bergami, University of Siena; M.P. Monopoli, University College Dublin / Centre for BioNano Interactions School of Chemistry and Chemical Biology; K.A. Dawson, University College Dublin / Centre for BioNano Interaction School of Chemistry and Chemical Biology; I. Corsi, University of Siena / Department of Physical Earth and Environmental Sciences; L. Canesi, university of genoa / DISTAV

Nanoparticles (NPs) released into the environment can undergo considerable transformations before reaching the target biological system: however, the evaluation of the biological effects of NPs requires additional understanding of how, once within the organism, NPs interact at the molecular level with cells in a physiological environment. In mammalian models, interactions of NPs with plasma proteins originate a coating known as protein *corona* (Monopoli et al., 2011, J Am Chem Soc 133:2525). The corona proteins control the specific cellular receptors for particle recognition, the internalization pathways, and the immune response. Formation of a NP corona has been recently reported also in terrestrial and freshwater invertebrates; however, no information is available in marine species. PS NPs can occur in the marine environment as degradation products of macro- and microplastics. Recent studies on the marine bivalve *Mytilus* showed that cationic PS NPs (PS-NH_2, 50 nm) affect different functional parameters of the immune cells, the hemocytes. In vitro exposure to PS-NH_2 in ASW medium decreased phagocytic activity and increased lysosomal enzyme release, extracellular oxyradical and nitric oxide production, with maximal effects at lower concentrations (1-5 μg/ml). Only at higher concentrations (50 μg/ml) lysosomal damage and induction of pre-apoptotic processes were also observed (Canesi et al., 2015, Mar. Environ. Res. 111:34). In this work, the effects of mussel hemolymph serum on the interactions between PS-NH_2 and hemocytes were evaluated. Cells were exposed for 5 - 60 min to PS-NH_2 suspensions in hemolymph serum (1, 5, 50 μg/ml). In the presence of serum, PS-NH_2 increased lysosomal damage and extracellular oxyradical production with respect to ASW medium. These effects were associated to an opposite trend in the activation state of p38 MAPK, a key component of immune signaling, in serum and ASW, respectively. Moreover, TEM observations indicate a general increase in cellular damage induced by opsonized PS-NH_2. The results show that soluble serum components can affect interactions of PS-NH_2 with *Mytilus* hemocytes, and suggest that a NP-protein corona might also be formed in biological fluids of mussels. The results underline the need of understanding how the formation of a NP protein corona may affect the biological outcome of in vivo NP exposure in marine invertebrates.

TU037

Exposure to sublethal concentrations of metal nanoparticles may lead to disturbed feeding behavior and elevated metal body burden of Daphnia magna

M. Heinlaan, M. Muna, H. Vija, National Institute of Chemical Physics and Biophysics; V. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel; A. Kahru, National Institute of Chemical Physics and Biophysics / Environmental Toxicology

In ecotoxicological studies of metal nanoparticles (MNPs), lethality is the most often addressed acute toxicity endpoint and aquatic crustaceans are often used as test species. Freshwater biota and *Daphnia magna* in particular, is one of the most vulnerable targets of MNPs mainly due to high sensitivity of *D. magna* to heavy metal ions, released from the MNPs, but also due to its physiology (e.g. feeding). Though significant for viability of the zooplankton population and the ecosystem health, sublethal effects of MNPs such as affected feeding are remarkably less studied. The aim of the current study was to evaluate whether the exposure to sublethal concentrations of MNPs affects *D. magna* feeding on microalga *Chlamydomonas reinhardtii* later on and whether there exists a risk for trophic transfer of MNPs (from *D. magna* to higher organisms). To evaluate the solubility-related effects of the studied MNPs, the respective soluble metal salts were studied in parallel. To obtain dose-response data, *D. magna* was exposed to Ag, CuO, Co_3O_4 and Mn_2O_3 NPs and the respective metal salts for 48h according to OECD202 guidelines. The tested concentration range for Ag NPs was 0,1-20 µg Ag/L and for other MNPs 0,01-100 mg metal/L. After the 48h chemical exposure, *D. magna* (from sublethal exposure concentrations) feeding on microalgae was assessed by algal autofluorescence in flow cytometry. In parallel, trophic transfer potential of metals upon exposure to sublethal concentrations of the studied chemicals was evaluated by quantifying the total body burden of metal in NP/salt-exposed daphnids i) immediately after exposure and ii) after post-exposure feeding using Total Reflection X-ray Fluorescence spectroscopy (TXRF). The 48h toxicity for *D. magna* decreased in the following order: Ag>>CuO>>Co_3O_4=Mn_2O_3 and $AgNO_3$>>$CuSO_4$>>$CoCl_2$•$6H_2O$>$MnCl_2$•$4H_2O$ for MNPs and the soluble salts, respectively. Co_3O_4 and Mn_2O_3 NPs were non-toxic up to 100 mg metal/L. Flow cytometry and TXRF proved suitable tools for studying the chosen endpoints. Results of the post-exposure feeding assessment showed decreased feeding of previously MNP-exposed daphnids compared to the metal salt exposed ones. TXRF analyses of MNP-exposed organisms showed that post-exposure feeding significantly decreased the total metal body burden nevertheless it remained elevated compared to that of unexposed control daphnids. Acknowledgements: This study was supported by Sciex NMS^{CH} project 13.143 (MH), by ETF9347 and by IUT23-5.

Effects of graphene oxide on aquatic macrophyte under the influence of humic substances

C.M. Jonsson, Embrapa Environment, Brazilian Agriculture Research Corporation / Ecotoxicology and Biosafety Laboratory; Z. Clemente, Embrapa Meio Ambiente / Laboratory of Ecotoxicology and Biosafety; V. Castro, Embrapa Environment / Ecotoxicology and Biosafety; R.F. Castanha, Embrapa Environment, Brazilian Agricultural Research Corporation / Laboratory of Ecotoxicology and Biosafety; J.H. Vallim, Embrapa Environment, Brazilian Agriculture Research Corporation / Ecotoxicology and Biosafety Laboratory; N. Domingos, Embrapa Environment, Brazilian Agricultural Research Corporation / Laboratory of Ecotoxicology and Biosafety; S. Blumel, Embrapa Environment, Brazilian Agriculture Research Corporation / Ecotoxicology and Biosafety Laboratory

The behavior of nanostructured graphene oxide (GO) in the environment is complex and must be completely understood to evaluate the risk involved. Studies show that humic acid (HA) can stabilize nanomaterials in water and change its behavior. The aquatic macrophyte duckweed (*Lemna minor*) is a good plant model for adverse effects evaluation of many test-materials due to its fast growth and small size. This study assessed the effect of GO, with and without HA, on the growth of *L. minor* on fronds number and biomass changes. The plants were exposed during 7 days to the nominal concentrations of GO equals to 0.0 (control), 0.1, 1.0, 10.0 and 100.0 mg L-1, in the absence or in the presence of 20 mg L-1 of HA. Tests were conducted in multiwell polystyreneplates where each well contained two fronds at the start of the experiment. The number of replicates for each test–concentration was 24 wells. The plants were exposed to a constant photoperiod (24:0, light:dark cycle) supplied by white fluorescent lamps (~700 lux) at the temperature of 20± 2 ºC. The fronds number was counted daily and the wet weight was assessed at the end of the experiment. The concentration that promoted 50% of inhibition in the growth rate in terms of fronds number ($EC50\text{-}7d_{growth}$) and the concentration that promoted 50% of wet weight reduction ($EC50\text{-}7d_{biomass}$) were calculated. The reduction of the growth rate by GO at the concentration of 100 mg L-1 was remarkable detected ($P < 0.001$) in the absence of the humic substance (HA). The HA seems to contribute with such reduction because this effect was also observed at the GO concentrations of 1.0, 10.0 and 100.0 mg L-1 in the presence of the humic substance ($p< 0.01$, $p< 0.001$ and $p< 0.001$, respectively). Although, the calculated $EC50\text{-}7d_{growth}$ for these exposures, with and without HA, was >100 mg L-1. This value attributes a practically non-toxicity for the test-material in terms of fronds production. On the other hand, the calculated $EC50\text{-}7d_{biomass}$ for the GO in the presence of HA or not was 2.8 and 2.4 mg L-1 respectively. These results indicate that the adverse effects of GO in *L. minor* are more pronounced on the biomass production since it was clearly observed that reductions in the fronds sizes were greater than in the fronds number. The $EC50\text{-}7d_{biomass}$ values assigns a moderate toxicity of GO to *L. minor* and these data may be useful for the establishment of maximum concentrations limits of this material in water bodies. **FAPESP proc 2014/01995-9, 2014/12891-0 \n**

Toxicity of engineered silver nanoparticles (NPs) is enhanced by co-exposure with clay particles in zebrafish larvae

C.C. Liddle, S. Renton, Heriot Watt University / School of Life Sciences; H. Johnston, Heriot Watt University / Life Sciences; T.F. Fernandes, T. Henry, Heriot-Watt University / School of Life Sciences

Naturally occurring particulates within the nano-size range are very abundant in surface waters and among these are mineral clay particles. Engineered nanoparticles (NPs) that are released into surface waters will undoubtedly interact with naturally occurring particulates; however, investigations of the effects of these interactions on NP toxicity have not been conducted. Clay minerals consist of silica tetrahedral (T) and alumina octahedral (O) layers in a lamellar structure that results in patch-wise surface heterogeneity with both positive and negative charges on their surfaces. The presence of both polarity charges on the surface of clay particulates suggests that interactions with silver (Ag) NPs with a negative zeta potential and dissolved free silver ions (Ag^+) will occur. We hypothesised that interactions between Ag-NPs and clays would alter aqueous phase Ag-NP toxicity in zebrafish *Danio rerio* larvae (ZFL). Parallel Ag-NP (0-3 mg/l) suspensions were prepared with and without 20 mg/l of Kaolinite clay suspension, and zebrafish larvae were exposed for 96 h (age 72-168 h post fertilization). Consecutive experiments were conducted with increasing concentrations of clay and humic acid (0-100 mg/l) and fixed concentrations of Ag-NPs (0.75, 1, 1.5 and 2 mg/l), and mortality of larvae was recorded. The clay exposed controls showed no toxicity from clay alone. Mortality of ZFL significantly increased when fish were exposed to both Ag-NPs and clay. The toxicity of 1 mg/l Ag-NPs increased with clay concentration by up to a maximum increase of 0.4 fold with 60 mg/l of clay, relative to 1mg/l of Ag-NP only. The 96-h Ag-NP exposure concentration predicted to kill 50% (LC_{50}) of ZFL with and without clay (20 mg/l) was 0.73±0.1 and 1.1±0.1 mg/L (±SEM) respectively, which is a 0.66 fold increase in toxicity within the clay and Ag-NP co-exposure. Humic acid significantly decreased toxicity of Ag-NPs (consistent with previous reports); however, the presence of humic acid did not eliminate the increased toxicity of Ag-NPs when co-exposed with clay. The observed increased toxicity of Ag-NPs in ZFL when co-exposed with clay is environmentally relevant and a novel result that suggests an alternative facet regarding the environmental effects of engineered nanoparticles.

TU040

Graphene oxide toxicological effects on daphnia and hydra

V. Castro, Embrapa Environment / Ecotoxicology and Biosafety; Z. Clemente, Embrapa Meio Ambiente / Laboratory of Ecotoxicology and Biosafety; D.S. Martinez, Brazilian Center for Research in Energy and Materials / Brazilian Nanotechnology National Laboratory; C.M. Jonsson, J.H. Vallim, S. Blumel, Embrapa Environment, Brazilian Agriculture Research Corporation / Ecotoxicology and Biosafety Laboratory

The increased use of nanomaterials products requires robust strategies to identify risks when they are released into the environment. Graphene and its derivatives are promising candidates for biomedical applications and as potential advanced water purification agents. However, little is known about their ecotoxicological risks. Aquatic toxicity tests are performed with different aquatic organisms as daphnia and hydra in order to evaluate the risks resulting from the presence of graphene oxide (GO) in the environment. The following GO concentrations were tested: 0, 1, 10 and 100 mg.L^{-1}. Acute toxicity to D. magna was evaluated in a period of 48 hours when was recorded the number of moving subjects in order to determine the CE5024h and CE5048h (n = 24 / group). The percentage of daphnia presenting mobility after 48 hours of exposure was greater than 60% in all groups. There was a concentration effect of graphene oxide ($p = 0.02$) and mobility was 20% lower in group exposed to 100 mg.L^{-1} than the control group. To evaluate the occurrence of the effect of sublethal concentrations for 96 h, it was evaluate neonate *D. similis* growth rate through exposure to the same conditions used for acute toxicity testing (n = 10 / group). The bodies were photographed at the start of the test and every 24 hours. Also, there was studied the effect of the organisms mobility during 96 hours calculating the median survival time of the population, defined as the average time between the start of exposure and the immobility of organisms. There was a sharp decline when the organisms were subjected to 100 mg. L^{-1} GO. The *Hydra attenuata* test was performed for 96h. The organisms were observed every 24 hours for the presence of changes ranging from tentacles with bulbs (low toxicity) till shortening of the tentacles (severe toxicity), tulip aspect and disintegration (lethal). A mean score for each concentration was calculated. No mortality was observed in any concentration tested. However, it was observed some morphological alterations after 72h of 100.0 mg.L^{-1} exposure as clubbed and shortened tentacles and body slightly contracted. Exposures of the test organisms indicate that GO do not present a lethal risk or adversely affect them at concentrations lower to 10.0 mg. L^{-1}. Even though the results apparently demonstrate that GO currently do not pose a serious risk, it may exert some damage in aquatic organisms tested at higher doses. **FAPESP proc 2014/01995-9, 2014/12891-0**

Ecotoxicological effect of graphene on the benthic freshwater diatom Nitzschia palea

M. GARACCI; J. Silvestre, ECOLAB UMR CNRS UPS INPT / ECOLAB UMR CNRS UPS INPT; F. Mouchet, ECOLAB UMR5245 CNRS UPS INPT / Ecotoxicology and Environmental Health; C. SARRIEU, E. Flahaut, CIRIMAT UMR CNRS 5085 UPS INPT; L. GAUTHIER, ECOLAB UMR5245 CNRS UPS INPT; M. Barret, E. Pinelli, ECOLAB UMR CNRS UPS INPT

Carbon-based nanoparticles such as graphene have many applications in different fields due to their outstanding electrical, optical and mechanical properties leading to their industrial production. Thus, few-layer graphene nanoparticles (FLG), composed of 1 to 4 planar carbon layers, are likely to be found in the environment and especially in rivers. In this study, the ecotoxicological effect of FLG on the freshwater benthic diatom *Nitzschia palea* was assessed. The experimental design used allowed to distinguish the shading effect from the total effect of exposure to FLG on *N. palea*,where diatoms are directly exposed to nanoparticles. A large range of concentrations was tested (0.1, 1, 10 and 50 mg.L^{-1} of FLG).To assess the effect of FLG on diatoms, several toxicity markers were evaluated such as growth rate, mortality and the photosynthetic activity. An inhibition of the growth rate of diatoms exposed to 50 mg.L^{-1} of FLG was observed 48 h after the beginning of the exposure, revealing a significant toxicity. In these conditions, the growth inhibition was associated with an increase in diatoms mortality. After 48 h of FLG exposure, a shading effect was observed on the cellular growth for culture exposed to the highest concentration of FLG. However, after 144 h of exposure, the growth rate was recovered, revealing a decrease in diatoms mortality, which can be explained by FLG stuck on the biofilm. *N.palea* naturally produces biofilm by excreting exo-polymeric substances (EPS) which can help diatoms to grow on the substrate. Indeed, EPS analysis by Alcian blue coloration and Scanning Electron Microscopy observation allowed us to conclude that EPS produced by diatoms strongly interact with FLG, sticking nanoparticles at the bottom of the well. These observations could explain the growth rate recovery at the end of the experiment in the total exposure conditions. In our experiments EPS secretion contributed to clarify the water column and reduced the physical interaction between FLG and diatoms to avoid the contamination. Overall, these results suggest that one potential toxicity process of graphene could be a combination of direct and shading effect leading to a strong interaction between biofilm and nanoparticles. Our results highlight the potential mechanisms of clarification of the water column by diatoms biofilms in natural ecosystems, by sticking FLG even at high concentration, which can correspond to an overflow accident condition.

TU042

Tissue specific responses of the Cape river crab, Potamanautes perlatus, to silver nanoparticles and temperature

C. Walters, CSIR / Natural Resources and the Environment; E.J. Pool, University of The Western Cape; V. Somerset, CSIR

Silver nanoparticles (AgNPs) are incorporated into an increasing number of consumer products. However, the potential toxicity of AgNPs to aquatic organisms is largely unknown. The behaviour of AgNPs is influenced by several factors, such as the inherent properties of the NP (size, shape, surface area, surface charge, crystal structure, coating, and solubility/dissolution) and environmental properties of the dispersed media (temperature, pH, ionic strength, salinity, organic matter). In the aquatic environment, the collective effects of various stressors that act on similar pathways (such as toxicity, oxidative stress responses) confound the assessment of responses to NP. It is, therefore, important to study the effects of AgNPs in the context of other common environmental stressors (such as temperature). In this study, freshwater crabs were exposed to varying concentrations of AgNPs and varying temperatures for 7 days and the effects of a suite of biomarkers of oxidative stress were evaluated. Biomarkers of oxidative stress were investigated in the tissues (gills, hepatopancreas, haemolymph, haemocytes and muscle) in a freshwater crab species, the Cape river crab *Potamanautes perlatus*. A cytochrome P450 assay was used as an indicator of metabolism. Superoxide dismutase (SOD), catalase (CAT) and glutathione s-transferase (GST) assays were used as indicators of impacts on antioxidant capacity. The results indicated that the haemolymph are more susceptible to oxidative stress originated by AgNP and temperature stress, whereas the gills constitute the main storage organ for Ag. These tissue specific differences in toxicity to AgNPs reflect distinct nanoparticle effects. The results further concluded overall that AgNPs and elevated temperature in the environmentally relevant range increased the toxicity and cellular responses in the crab.

Bioaccumulation of Silver and Silver Nanoparticles in Earthworms
J. Velicogna, D. Schwertfeger, Environment Canada / Biological Assessment and Standardization Section; R. Scroggins, Environment Canada; J. Princz, Environment Canada / Biological Assessment and Standarization Section
Engineered silver nanoparticles (AgNP) are the most common form of nanomaterial found in commerce today. It is expected that these materials will end up in soils via the waste water stream through the application of biosolids to agricultural soils. Earthworms are an important part of the soil ecosystem and effects on their ability to reproduce or the possibility for bioaccumulation and subsequent trophic transfer is of concern. Three bioaccumulation tests were performed with *Eisenia andrei* in an agricultural sandy-loam soil: poly-disperse Ag nanomaterial comprised of 2 nm particles (0.3% PVP), silver nitrate ($AgNO_3$), and dispersed 40 nm AgNP (80% PVP) aged in biosolids prior to mixing with soil. For each test, *E. andrei* were exposed to the contaminated soil for an uptake period of 21 days and then transferred to a clean soil for an elimination period of 21 days. The results of the bioaccumulation indicate bioaccumulation factors (BAF) of AgNP > $AgNO_3$ > AgNP in biosolids (in order of significant bioaccumulation). In the cases whhere the soils were not amended with biosolids, the measured silver in earthworm tissue remained significantly greater than background after the elimiation period, whereas *E. andrei* in soils amended with AgNP contaminated biosolids eliminated the silver back to background levels.

TU044
Influence of surface characteristics on graphene oxide toxicity for zebrafish embryo
Z. Clemente, Embrapa Meio Ambiente / Laboratory of Ecotoxicology and Biosafety; V. Castro, Embrapa Environment / Ecotoxicology and Biosafety; D.S. Martinez, Brazilian Center for Research in Energy and Materials (CNPEM) / Brazilian Nanotechnology National Laboratory LNNano
Despite nanotoxicological studies have been intensified in recent years, gaps remain in the methods used to assess the nanotechnology risks. These gaps are due to the complex nanomaterials behavior in the environment, especially in the presence of organic matter and depending on the nanomaterial characteristics. Studies indicate that humic acid present in the aquatic environment can increase the stability of nanomaterial dispersions and may change its toxicity to aquatic organisms. The adsorption of oxidative debris (carboxylated carbonaceous fragments - CCFs) has also been discussed as an important factor influencing GO properties and behavior. The surface characteristics of GO can influence its biotechnological application as well as its toxicological effects. The aim of this study was to evaluate the influence of the presence of oxidative debris and humic acid in the toxicity of graphene oxide (GO) utilizing Fish Embryo Toxicity Test (FET test). GO (Sigma Aldrich) was refluxed with NaOH (0.01M, 1h, 90ºC) and HCl (0.1M, 1h, 90ºC) to produce GO without debris (GOwd). GO And GOwd were characterized through spectrophotometry, dynamic light scattering and atomic force microscopy. Zebrafish embryos (*Danio rerio*) were exposed during 96 h to 100 mg.L^{-1} GO or GOwd, in presence or absence of humic acid (HA, 20 mg.L^{-1}). A control group exposed to reconstituted water was also performed. At the end of the exposure period, the larvae were measured and frozen at -20ºC for subsequent evaluation of acetylcholinesterase activity (AchE). We also performed an *in vitro* test to evaluate direct effect of the nanomaterial in zebrafish AchE activity. Homogenates of zebrafish larvae were incubated with GO and GOwd at 30 mg/L (20 min, 30ºC) before AchE assay was performed. Both GO agglomerated and precipitated quickly in reconstituted water. The presence of HA in the medium stabilized the GO suspensions similarly to that occurred with GO in ultrapure water. There was no difference between groups related to the occurrence of embryo malformation or mortality. Larvae exposed to GO were shorter and showed lower AchE activity than control and group exposed to GOwd. The *in vitro* test showed that the nanomaterial did not inhibit AchE activity. The nanomaterial showed low toxicity to embryo, but the reduction in total length and AchE activity in the organisms can be due to indirect effects in zebrafish development. More experiments will be performed to understand those effects.

TU045
Critical assessment of a 10 day sediment toxicity and bioaccumulation study of nano silver and silver nitrate using the polychaete Arenicola marina.
M. Fox, M. Sanders, Cefas / Environment and Animal Health; D. Doran, D. Sheahan, Cefas
There is an increasing use of Silver Nanoparticles (Ag-NPs) in various industry sectors, which are entering the marine environment via sewage treatment plants. Marine and estuarine sediments are thought to be a sink for the Ag-NPs as well as a food source for the polychaete worm, *Arenicola marina*. The two objectives of this study were to measure the bioaccumulation and toxicity of Ag-NPs to *Arenicola marina* and to assess the methodology used for sediment exposures for nanoparticles (NPs). Survival and cast production were assessed over the 10 day test duration. The toxicity and bioaccumulation of ionic silver was also assessed as a comparison. Chemical analysis of the sediment, overlying water and test organisms was conducted to detect silver concentrations using ICP-MS. The sediment silver concentrations ranged between 116 and 146% of nominal concentrations for the Ag-NPs tested. This shows that the particles remain in the sediment portion of the test system and are available to the test organism via ingestion of sediment. Silver was detected in the *A. marina* exposed to the higher concentrations tested, these treatments were also associated with low survival. Therefore there is uncertainty if the silver detected was due to bioaccumulation in the tissues or to sediment within the gut of the worms as depuration was not possible. The median lethal concentration (LC_{50}) is defined as the concentration resulting in 50% mortality of the *A. marina*. The Ag-NPs LC_{50} value for survival was 25.2 (22.5-28.3) mg/kg compared to 8.7 (5.2-14.5) mg/kg for ionic silver. The higher LC_{50} value for Ag-NPs suggests that they were less toxic than the ionic silver in this study. The Ag-NPs EC_{50} value for cast production was 13.9 (11.6-16.6) mg/kg compared to 10.4 (8.4-12.9) mg/kg for ionic silver. The second objective of this study was to assess the methodology and its suitability for nanoparticle toxicity assessment. The study used a direct spiking technique rather than solvent spiking to a dry sediment portion due to the nature of the test material. The spiking method was successful for this study, shown by the measured concentrations detected relative to the target values. However nanoparticles are produced in many different sizes, with and without coatings, in solid or liquid state and can agglomerate. All of these factors can pose problems when trying to spike sediments for toxicity testing therefore the specific approach may need to be adapted on a case by case basis.

TU046
Uptake of sediment-associated Ag nanoparticles in oligochaetes - a first step towards trophic transfer?
S.R. Tangaa, Roskilde University / Science Environment; M. Winther-Nielsen, DHI / Environment and Toxicology; H. Selck, Roskilde University / Dept Environmental Social and Spatial Change
Metal-containing engineered nanoparticles (Me-ENPs) are used in a wide range of products worldwide, such as inks, plastics, consumer products, lubricants, electronics and bioactive coatings. These particles will ultimately end up in the aquatic environment and have been shown to be taken up by a variety of species, from both water and sediment. Yet, research on potential trophic transfer of ENPs in aquatic ecosystems is limited. This study is the first in a series of experiments leading to the identification of trophic transfer of metal-based ENPs in freshwater environments. The main outcome of the study is the determination and quantification of ENP bioaccumulation in sediment-dwelling organisms, which will add to our understanding of this first step in the benthic food chain and thus of the potential trophic transfer of ENPs. Preliminary studies have shown that the oligochaete *Tubifex tubifex* accumulates Ag-ENPs from sediment after long-term exposures (28days). In this study, we investigate whether this bioaccumulation pattern also occurs after acute exposure (72-96h) to sediment spiked with different Ag-ENP concentrations. Ag-ions and a particulate reference are used to be able to pin-point potential nano-specific effects. The overall aim of the study is to determine the first step in food chain transfer of Ag-ENPs, using sediment as primary contaminant source. Considerations regarding acute vs. chronic exposure durations is made in relation to experimental design and bioaccumulation.
ICP-MS is used to analyze the degree of uptake in *T.tubifex*, estimated based on total metal uptake in organisms after exposure. The concentration range of Ag-ENPs is covering both low, environmentally realistic and higher, more response-inducing concentrations. Information on experimental setup, preliminary results and ideas for future research, including the next steps in the food-chain transfer investigation will be presented. We believe that by knowing if and to what degree aquatic organisms accumulate ENPs, a greater understanding of the actual risk and trophic transfer potential of these contaminants will be achieved.

Silver nanoparticles inhibit the embryonic development of Daphnia galeata
R. Cui, Konkuk University; Y. An, Konkuk University / Department of Environmental Heath Science
Silver nanoparticles are widely used in various commercial and industrial applications; therefore, it is evident that they are already widely distributed in water environments. This study investigated the adverse effect of silver nanoparticles to the embryonic development of water flea. Test species is *Daphnia galeata*, which inhabits Holarctic lakes and rivers, and have sharp head, and are smaller in size than *Daphnia magna*.Embryos were extracted from *Daphnia galeata* adult female, and stage two embryos were selected, and exposed to a series of AgNPs concentrations for 72 hours. We measured a range of embryonic endpoints including antennae, eye, rostrum, heart, carapace, post abdominal claw, malpighian tube, sensory bristles, and tail spine. In addition, *Daphnia galeata* neonates were exposed to 50 nm of AgNPs for 48h hours. As a result, the EC50 value for neonate immobilization was estimated to be 38.42 ug/L. The 50 nm of AgNPs of 0.04 mg/L have serious inhibition of embryonic development. Further research is needed to investigate multiple species of water fleas which are important consumers in aquatic food chain. *Acknowledgements. This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (2013R1A1A2061386), and the Ministry of Science, ICT and Future Planning (2014R1A2A1A11050513).*

Investigating the Effects of Nano Copper Oxide on Plants, Collembola and Earthworms in Soil

J. Velicogna, C. Beer, A. Jesmer, Environment Canada / Biological Assessment and Standardization Section; C. Fraser, H. Lemieux, Environment Canada / Biological Assessment and Standarization Section; D. Schwertfeger, Environment Canada / Biological Assessment and Standardization Section; R.P. Scroggins, Environment Canada / Biological Methods; J. Princz, Environment Canada / Biological Assessment and Standarization Section

Copper nanomaterials have a wide range of uses in agriculture (biocides, wood preservatives), electronics (conducting material), household (biocide), and industrial (catalysts, conductive) applications. The variety of applications and usage can results in these nanomaterials ending up in the soil environment either directly (i.e., leaching of treated wood products or release from agricultural practices) or via the waste water stream through the application of biosolids. A suite of soil toxicity tests were completed to examine and compare the effects of nano copper oxide (nCuO) to ionic copper (Cu^{2+}, as $CuSO_4$) in a sandy-loam agricultural soil both with and without biosolid amendments. Plant tests examined effects on emergence and root and shoot growth (length and dry mass) of *Elymus lanceolatus* and *Trifolium pratense*. Invertebrate tests examined survival and reproduction in *Folsomia candida* and *Eisenia andrei*, as well as bioaccumulation for *E. andrei*. Tests were conducted at a range of test concentrations encompassing environmentally relevant concentrations at the low end as well as high concentrations in order to record effect levels. Test soils were measured for total Cu concentrations (HNO_3 digest/ICP-MS analysis) and Cu^{2+} activity (KNO_3 extraction/analysis by Cu^{2+} -selective electrode) to elucidate the source of observed effects as being a result of the nanomaterial or released Cu^{2+}.

Lifecycle and Impact of Sunscreens Using TiO2 Nanomaterials

J. Labille, CNRS; D. Slomberg, Labex Serenade/CEREGE/Aix-Marseille Université; D. Guerin, Laboratoires Biocos; J. Hubaud, Helioscience; S. Lehmann, ISTerre UJF; L. Hedouin, CNRS CRIOBE; V. Matranga, CNR IBIM; S. Motellier, CEA Liten; C. Santaella, CNRS/CEA/Aix-Marseille Université / Bioscience and biotechnology Institute of Aix Marseille; I. Capron, INRA BIA; A. Glaser, Novancia; P. Hennebert, INERIS; C. de Garidel-Thoron, CNRS AMU CEREGE

Among cosmetics and personal care products, sunscreen products are of emerging concern regarding both human and environmental health. The fate and impact of mineral nanoparticulate UV-blockers, such as TiO_2 nanomaterials, is under consideration from a regulatory perspective due to their potential impact. Once leaving the skin either through bathing or everyday usage and cleaning, the nanomaterials contained in the sunscreen can be released into rivers, lakes, sea shores, and/or sewage treatment plants. The nanomaterial behaviour, fate and impact in these different systems is largely determined by its surface properties, (e.g. the nanomaterial coating type) and lifetime. Here we present the first result of the Eco-SUN research program aimed at developing the eco-design of sunscreens through the minimization of risks associated with nanomaterials incorporated into the formulation. Different stages of the cream lifecycle are considered from its manufacture to its end of life, through its use by the consumer and its impact on the exposed environments. Reducing the potential release and / or toxicity of the nanomaterial from the cream is a decisive criterion for its eco-design. Different relevant TiO_2 UV-blockers have been selected to integrate a typical o/w formulation as case studies. The resulting sunscreen were characterised in terms of nanomaterial localisation, sun protection factor and photo-passivation. The risk for the consumer by dermal exposure was assessed using skin biopsies. Inflammation and skin penetration were evaluated. The risk for the aquatic environment directly expose was assessed both in terms of exposure and hazard. The release of nanomaterials from the sunscreen upon normal usage was studied in laboratory through simulated aging procedure. Two biological models, sea urchin and coral colonies, were selected as relevant endpoints to assess the marine ecotoxicity of the byproducts formed. Finally, the risk related to the end of life of the sunscreen through the removal with cleaning water followed by drainage to sewage treatment plants was evaluated by considering two opposite fate scenarios: (i) nanomaterial concentration in sewadge sludge later spread as fertilizer in agriculture, and (ii) nanomaterial suspension maintained in the treated water and released in river water. Thus, fate and impact in soil and river ecosystems were also studied.

TU050

Testing toxicity of graphene oxide in zebrafish embryos

F. Hernández, Somaprobes; I. Irijalba, BBD BioPhenix-Biobide; A. Muriana, BBD BioPhenix-Biobide / RD; C. Quevedo, BBD BioPhenix-Biobide

Due to their unique physiochemical properties, two dimensional graphene oxide (GO)-based materials have attracted considerable attention both in research community and industry. With the more application of this nanomaterial in the production of goods used in our daily life, it is increasingly released into the environment. However, the health risks associated with environmental exposure to GO are largely unknown, particularly with respect to embryogenesis. Zebrafish embryos is an alternative model for the evaluation of developmental toxicity of chemicals during early life stage with the characteristics of small-scale, high throughput and easy observations. In this study, 4 hours-postfertilization (hpf) zebrafish were treated with 8 concentrations of GO (water dispersion): 0.1, 0.3, 1, 3, 10, 30, 100 and 300 mg/L. A hole in the chorion was performed with a thin needle to prevent toxicity induction by hypoxia due to graphene adhesion to the chorion. Embryos were analyzed daily until 4 days post-fertilization (dpf) and not toxicity manifestations or lethality were observed at any of the concentrations tested. To guarantee the uptake of graphene, a second experiment in which grapehene was injected was carried out. Two concentrations were selected, 3 mg/L, the concentration from which aggregation of graphene was clearly detected in the first experiment and one lower concentration, 1 mg/L. Toxicity manifestations were not detected in this case either, what indicates that graphene is probably not toxic for zebrafish embryos, at least in the conditions used in this study.

TU051

Assessing the influence of cationic and hydrophobic modifications in the ecotoxicity of hydroxyethyl cellulose polymers.

A.M. Simões, CESAM & Department of Biology / Department of Biology; C. Venâncio, Department of Biology / Biology; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; F.J. Antunes, University of Coimbra, Department of Chemistry / Department of Chemistry; I. Lopes, University of Aveiro / Biology Department CESAM

New highly charged polymers have been developed within the industry of personal care products, aiming at better performances for conditioning and deposit beneficial ingredients onto hair and skin. Among these, SoftCat^{TM} proved to be more efficient than conventional cationic polymers. They are polymers based on quaternary ammonium salts of hydroxyethyl cellulose and include several families of cationic products that differ in both viscosity and charge. SoftCAT SK comprise four high viscosity polymers that incorporate variations in charge level and hydrophobic modification while SoftCAT^{TM} SL constitute four high viscosity polymers that incorporate low levels of hydrophobic modifications. It has been shown that these variations in architecture correspond to different performances. In the present work is hypothesised that such differences in architecture are also associated with different ecotoxicological effects. If such association is detected the investment on the less toxic variation could be recommend to the industry. To test the above hypothesis, the following standard toxicity assays were carried out for each variation of SofCats^{TM}: bioluminescence inhibition with the bacteria *Vibrio fisheri*, the 72h-growth inhibition with the freshwater microalgae *Raphidocelis subcapitata,* fish embryo acute toxicitytest with the zebrafish(*Danio rerio*)and the acute immobilisation test with *Daphnia magna*. The results suggest that the variations of SoftCAT SL showed the highest toxicity in relation to SoftCAT SK in *Raphidocelis subcapitata, and Daphnia magna* species. Preliminary tests with zebrafish also suggest that the SoftCAT SL variation is the most toxic. However, further studies are still needed to fully understand the adverse ecological effects of these types of polymers and allow suggesting which comprise the more environmental friendly solution simultaneously retaining the desired functions. Keywords: Hydrophobic modification, cationic substitution, SoftCAT, environmental friendly.

TU052

Phytoavailability of TiO2 and Ag Nanoparticles

C. Layet, Aix Marseille Université / Cerege; M. Auffan, CEREGE / International Consortium for the Environmental Implications of Nanotechnology; C. Santaella, CNRS/CEA/Aix-Marseille Université / Bioscience and biotechnology Institute of Aix Marseille; E. Doelsch, CIRAD

The development of Nanotechnologies and the nanomaterial's integration in current products asks the question of the behavior and transfer of these new elements in the different compartments of the environment. This implies to carefully study the soil/plant tranfer of nanoparticles at environmentally relevant concentrations, and to model their phytoavailability as a function of soil, plant, and nanoparticle properties. The present work aims at estimating the impact of these various parameters (clay content, organic matter concentration, pH, coating, shape and size of nanoparticle) on phytoavailability at environmental estimated concentrations. Since hydroponic cultures do not allow studying the soil/nanoparticle or soil/plant interactions, we used the RHIZOtest (ISO 16198), a biotest that allows cultivating plants on soil separated by a polyamide mesh (pore size: 30 μm). Tall Fescue (Fetusca arundinacea) was in contact with several soils contaminated with TiO2 nanoparticles with different shape and size (shere 5nm, cube 35 nm, rod 250 nm), and Ag0 (PVP coated and SiO2 coated) compared to silver nitrate. The concentrations for TiO2 nanoparticles treatment were 1, 15, 150 mg/kg in soils. The concentrations for Ag nanoparticles were 1.5, 150 and 1500 μg/kg in soils. The results of the silver RHIZOtest highliht a soil effect with Ag nanoparticles in term of flux of Ag in the roots. The Ag fluxes with the two soils having the greatest cationic exchange capacity are smaller the two other soils. There is no significant difference between all nanoparticle treatments comparing to silver nitrate treatment. The dissolution of the nanoparticle will be checked by hyperspectral microscopy on roots. The results of titanium RHIZOtest show that there is no significant difference between controls and 1 and 15 mg/kg treatments.

The treatments at 150 mg/kg show that there is no effect of size and shape of TiO2 on titanium flux in plant. Furthermore, there is no significant difference of flux considering the type of soil.

TU053

Physiological and biochemical responses of polychaete Diopatra neapolitana to Graphene oxide

L. De Marchi, University of Aveiro, Department of Biology & CESAM / Departamento de Biologia CESAM; V. Neto, Universidade de Aveiro, Portugal / Departamento de Engenharia Mecânica; R. Socoowski Britto, Universidade Federal do Rio Grande FURG, Brasil / Instituto de Ciências Biológicas; E. Figueira, CESAM University of Aveiro; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; R. Freitas, Universidade de Aveiro, Portugal / Departamento de Biologia CESAM

In the recent years there is an increasing concern about the large number of emerging pollutants that have been released into the environment without yet being regulated, such as carbon based nanomaterials (CBN).Graphene Oxide (GO) is one of the most important CBN that has been extensively used but, such as for most of the CBN, limited literature is available regarding the impacts induced in aquatic organisms by this pollutant. The polychaete *Diopatra neapolitana* has frequently been used to evaluate the impact of environmental disturbances in estuarine systems due to its ecological and socio-economic importance but, to our knowledge, no information is available on *D. neapolitana* physiological and biochemical alterations due to CBN exposure. Thus, the present study aimed to assess the toxicity effects of different concentrations of GO (0.01; 0.1; 1.00 mg/L) in *D. neapolitana* physiological (regenerative capacity) and biochemical (oxidative stress related biomarkers) performance, after a 28 days exposure period. The results obtained revealed that the exposure to GO induced negative effects on the regenerative capacity of polychaete specimens, with individuals exposed to the highest GO concentartion (1.00 mg/L) presenting the lowest capacity to regenerate their body and lowest glycogen levels. Furthermore, with increasing of GO concentrations *D. neapolitana* increased the lipid peroxidation (LPO), Glutathione S-transferase activity (GSTs) content and decreased the ratio between reduced (GSH) and oxidized (GSSG) Glutathione. The activity of the antioxidant enzyme catalase (CAT) was not significantly affected by GO changes, although a slight increase was noticed at the highest GO concentration. The activity of the antioxidant enzyme superoxide dismutase (SOD) was significantly higher at the 2 lowest GO concentrations, comparing to the remaining conditions. Overall, the obtained results indicated that GO induced alterations in the regenerative ability of *D. neapolitana*. In addition, GO induced oxidative stress responses in this species, evidenced by changes in indicators of cellular damage and antioxidant defenses, specially noticed at the highest GO concentration. Thus, *D. neapolitana* demonstrated to be a good bioindicator to monitor emerging pollutants such as GO.

TU054

Co-exposure to titanium dioxide nanoparticles does not affect cadmium toxicity in radish seeds (Rafanus sativus)

R. ROSHAN MANESH, G. Grassi, University of Siena / Department of Physical Earth and Environmental Sciences; e. bergami, University of Siena / Physical Earth and Environmental Sciences; L. Marques dos Santos, Universidade Federal da Paraíba / Departamento de Biologia Molecular; A. Atrei, University of Siena / Department of Biotechnology Chemistry and Pharmacy; I. Corsi, University of Siena / Department of Physical Earth and Environmental Sciences

Nanoparticles (NPs) are currently present in a variety of industrial products and their use, disposal and fate (degradation and/or persistence) into the natural environment require urgent investigations. Recent developments on environmental fate models indicate that as *nanowaste* they could reach both terrestrial and aquatic ecosystems thus potentially affecting environmental and human health. Plants can be therefore exposed to NPs but controversial toxicity results in terms of fate and toxicity are currently available. Furthermore, there is a current lack of information on complex interactions/transformations of the NPs, which might occur in the natural environment as for instance interaction with existing toxic compounds. As a consequence the prediction and assessment of NPs behaviour, exposure and biological effects represent a current major challenge. In the present study, radish seeds have been exposed to titanium dioxide NPs (n-TiO_2)(1-1000 mg/L)(P25, Aeroxide) and cadmium chloride (1-250 mg/L) alone and in combination using a seed germination and seedling growth toxicity test in radish *Rafanus sativus* (OECD 208). Seed germination was not affected by n-TiO_2 alone but a significant increase in root elongation was observed but not dose-dependently. On the opposite, $CdCl_2$ cause a dose-dependent inhibition on root elongation and a complete abolishment of seeds germination at the highest concentration of 250 mg/L. Co-exposure clear showed no interaction of n-TiO_2 in Cd effects both at high (250 -1000 mg/L of $CdCl_2$ and n-TiO_2) and low doses (1-1 mg/L $CdCl_2$ and n-TiO_2). The presence of n-TiO_2 seems not affecting the bioavailability of $CdCl_2$ to seeds and roots so thus the toxic effects were still evident. Based on literature, n-TiO_2 (anatase) is known to adsorb Cd on the surface of the NP and thus potentially increase its bioavailability. According to our data, this was not observed since toxic effects exerted by $CdCl_2$ on *R. sativus* seeds were the same in presence or absence of n-TiO_2. DLS analysis showed that n-TiO_2 tested concentrations were quite dispersed in Milli-Q water reaching NPs size of ~180 nm (Z-average) and primary Z-potential (-31.7mV) and PdI (0.3). Seeds exposed to n-TiO_2 showed a clear uptake n-TiO_2 in particular on young leaf and inside the root. Our results underline that further studies are needed in order to address any potential interactions of NPs with toxic pollutants present in soils able to cause phytotoxicity in plants.

A network perspective on experimental data of organic matter and inorganic nanoparticles in aquatic media

N. Sani-Kast, M. Scheringer, ETH Zurich / Institute for Chemical and Bioengineering; J. Labille, CNRS; P. Ollivier, BRGM; D. Slomberg, Labex Serenade/CEREGE/Aix-Marseille Université; K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering

Understanding the influence of natural organic matter (NOM) on the stability of engineered nanoparticles (ENPs) is essential for understanding the behavior of ENPs in the natural environment, since NOM can stabilize ENP dispersions or enhance the aggregation of ENPs. The effects depend strongly on the physicochemical properties of the NOM and the surface characteristics of the ENPs. Therefore, to improve the mechanistic understanding of ENP-NOM interactions, experiments should study diverse combinations of NOM and ENPs, as pointed out by recent reviews. However, many of the numerous experiments carried out up until now repeat already well-studied NOM and ENPs combinations; rather few experiments investigate unique ENP-NOM combinations not studied before or after. This tends to lead to an overall low diversity of ENP-NOM combinations investigated, contrary to what is required. In this study we assess the overall diversity of this experimental field in order to identify knowledge gaps and possible research needs. Using the fact that several NOM and ENPs are common between the different experiments, we connected the materials that were investigated in 255 peer-reviewed papers that studied the influence of NOM on ENPs in aquatic media in a network. In this network, each node represents either an NOM or ENP of a given type, and the link connecting any two given nodes means that the two were used in the same experiment. In this network, many high-degree nodes are linked to low-degree ones, resulting in segregation of the data; in many cases, a given NOM or ENP is found to be tested with a set of ENPs or NOM types that is almost unique to it. The most central nodes are by far the Suwannee River Humic Acid for NOM and TiO2 and Fe2O3 for ENPs. This indicates that these constituents are investigated in combination with the largest number of corresponding constituents, in a large number of experiments. Temporal changes in the network's topology show a decrease in the global diversity over the last 25 years. In particular, we observe a decrease in the diversity of the NOM types employed in the experiments, which indicates that the focus is mainly on the ENPs studied. Overall, the trend observed implies that the empirical basis for a better understanding of NOM effects on ENPs remains rather limited, since insights from new studies are obtained for increasingly similar combinations of materials.

Biocompatible hydrogel nanocomposites for new generation drug design

A. Aleksandryan, Hazardous Substances & Waste Policy Division / Head of Division; A. Tonoyan, State Engineering University of Armenia / Macrokinetics of Polymerization Processes Basic Research Laboratory; S. Davtyan, State Engineering University of Armenia / Chemical Technologies and Polymeric Nano Composites Basic Research Laboratory

Medicine is the most exciting area for nanotechnology application even in such pivotal field of healthcare as cellular level fight against tumors. Despite its advantages, nanotechnology causes concerns, as nanoparticles can cause harm if applied in some particular fields. Dangers are connected to development of artificial materials with new properties. It is still unknown: how these new materials will "behave" in the human organism, as genetic after-effects might be displayed in the long-term perspective. Biocompatible hydrogel nanocomposites were synthesized by the method of frontal polymerization (FP) on the base of acrylamide and colloid solutions of locally available fossils: bentonite, diatomite, etc. Polydisperse bentonite powder was treated with solution of linear polyacrylamide as a surface active substance enveloping the nano-scale particles with their colloid state subsequent emission from polydisperse suspension. Such treatment allowed to synthesize polyacrylamide nanocomposite hydrogels with bentonite nanoparticles. The resulting nanocomposite hydrogel possessed appropriate adsorption properties and prolonged desorption of medicinal preparations according to preset programme. Adsorption and desorption optimal conditions were studied in such drugs as G?ngleron, Voltaren, Naltrexone at appropriate temperature and pH corresponding to acidity of human stomach and gastrointestinal tract. The kinetics of drugs controlled release was studied in conformity with established requirements. The most important advantage of synthesizing mentioned nanocomposites in FP mode is their absolute non-toxicity due to specific features of frontal method of synthesis. Unlike the globally used technology, due to specifics of FP, not only ecological compatibility is ensured at PAHs synthesis process, but toxic acrylamide is absolutely absent in obtained hydrogels. Due to their safety the possibility for wide use in various fields of human activity is created. The PAHs are cross-linked polymeric structures capable of swelling with absorption of a large amount of moisture and active substances without destroying the original shape. A specific advantage of PAHs is ability to release absorbed substances into the environment. It is noteworthy that this method has great advantages not only from the point of view of its high efficiency, ecological safety, possibility to control initial process parameters for the purpose to regulate properties of the obtained product.

TU057
Dispersion and aggregation of carbon nanotubes in aqueous solutions of anionic surfactants
k. yang, Zhejiang University / Depart of Environ Sci
Dispersion and aggregation of CNTs in the aqueous environment are critical behaviors affecting their fate, bioavailability, and potential environmental and health risks. Bulk CNTs are generally aggregated and cannot be dispersed significantly in water or even in organic solvents. Surfactants are widely employed as dispersion detergents to prepare stably suspended CNTs for industrial applications. Therefore, for a better understanding of the mobility of CNTs in the environment, this work examined (i) whether bulk CNTs can be dispersed and stably suspended in the natural environment and (ii) whether surfactant-suspended CNTs can retain their stability in the natural environment. We observed that CNTs can be stably suspended in sodium dodecylbenzene sulfonate (SDBS) solution but not in water with assistant of sonication. Moreover, CNTs could not be dispersed and stably suspended in water and SDBS solution by shaking at 140 rpm, a mild agitation representative of the natural aqueous environment. Therefore, both SDBS and sonication play important roles in the dispersion of CNTs, with sonication breaking down large aggregates of SWCNTs, while SDBS adsorbed on the SWCNTs inhibits the coagulation and aggregation to maintain the stability of the suspension in water. Concentration of dispersed CNTs in the SDBS solution depended on the sonication energy, but not the sonication time or output power of the sonicator alone. The amount of dispersed CNTs was positively correlated with the concentrations of SDBS and CNTs, and the length of the CNTs. The optimal energy, i.e. the minimum energy supplied by sonication to achieve a saturated suspension of dispersed CNTs in the SDBS solution, was CNT diameter-dependent. Stably suspended CNTs in SDBS do not remain stable at the presence of cations (eg, Na+, K+, Ca2+ and Mg2+) after dilution. These observations suggest that CNTs will not travel long distances in significant concentrations in natural environment. Moreover, re-aggregation of suspended CNTs in the presence of cations was dependent on SDBS concentration but not CNT concentration.

Fate and uptake of nanopesticides in soil-earthworm systems
M. Mohd Anuar, University of York / Environment; A. Boxall, M. Hodson, University of York / Environment Department
Over the past few decades a significant body of work has been done to understand the ecological and health risks of synthetic pyrethroid pesticides (SPs). Recently the use of nano-encapsulated SPs has been proposed. As nanoparticles can behave very differently from dissolved chemicals, it is possible that the environmental fate, uptake and effects of these nano-formulated pesticides could be very different from the conventional SPs. This study therefore investigated the effects of nano-encapsulation on the fate and uptake of bifenthrin, a widely used third generation synthetic pyrethroid, in soil systems. Studies were performed, using OECD Guidelines, on five soil types with different properties (total organic carbon and texture) to determine dissipation half-lives in soil, soil-water partition coefficients and uptake and depuration in the earthworm *Eisenia fetida* using analytical grade bifenthrin, a conventional bifenthrin formulation (Capture LFR) and two nano-formulations. Persistence, sorption and uptake behaviour of all the study materials varied across soil types. Generally, the persistence, sorption and uptake of bifenthrin in the conventional formulation were similar to the behaviour of the non-formulated active ingredient. However, nanoencapsulation significantly affected the behaviour of the bifenthrin. Results for the two nanoformulations were similar to each other but these showed enhanced persistence, decreased sorption and increased rates of uptake and depuration in the earthworms compared to the analytical grade material and the conventional formulation. We therefore anticipate that the distribution and impacts of the nanoformulation in natural soil systems will be different from currently used formulations. The observed differences in persistence and sorption behaviour are possibly due to the polymer capsule 'protecting' the active ingredient from microbes and soil binding sites. Differences in uptake might be explained by differences in distribution of the bifenthrin within the organism (i.e. the nanoformulation is accumulating in the earthworm gut while bifenthrin in the conventional and non-formulated treatments is being internalised). *Keywords:* Synthetic pyrethroids; Nanoformulations; Bifenthrin; Earthworms

TU059
In vitro and in vivo effects of copper oxide nanoparticles and copper ions in Zebrafish (Danio rerio): Effects on Cells, Embryos and Fry
A. Thit Jensen, Roskilde University / ENSPAC; L. Skjolding, DTU / DTU Environment; H. Selck, Roskilde University / Dept Environmental Social and Spatial Change; J. Sturve, Department of Biological and Environmental Sciences
The use of engineered metal nanoparticles (NPs) is continuously increasing and so is the scientific body of evidence regarding toxicity of these particles. However, further information on toxic effects of metal NPs is still needed to assess whether these particles are more or less toxic compared to their ionic counterparts. Here, we compare the toxicity of CuO NPs with ionic Cu to zebrafish hepatoma cells (ZFL), embryos and fry. In the *in vitro* tests no significant cytotoxicity (cell death, decreased metabolic or cell membrane integrity) was detected for Cu ions or CuO NPs, though both Cu forms caused significant effects on production of reactive oxygen species (ROS) compared to the control. However, results show that both Cu ions and CuO NPs are toxic to zebrafish embryos and fry. Embryo mortality increased in both Cu ions and CuO NP treatments. 24 h LC_{50}s was about10 μM (≈0.6 mg Cu L^{-1}) for both treatments, whereas exposure to Cu ions at 50 µM (≈3 mg Cu L^{-1}) caused significantly higher mortality than CuO NPs (≈100 and ≈70 % respectively). Only Cu ions showed effect on fry mortality (24 h LC_{50} about 30 µM, ≈2 mg Cu L^{-1} for Cu ions and >200 μM, 12.7 mg Cu L^{-1} for CuO NP). Both Cu treatments affected fry behaviour so that swimming activity increased during light cycles and decreased during dark cycles. In general, Cu ions had significant impact on behaviour at lower exposure concentrations than CuO NPs. In conclusion, there is a marked difference in toxicity among different levels of biological organization. Toxicity of Cu ions was higher than for CuO NPs for embryos and especially fry, whereas no significant toxicity was observed for either treatment to ZFL cells. This study shows that the release of metal NPs into the environment may have adverse effects on fish and possibly other aquatic organisms.

TU060
The interaction of silver nanoparticles with exopolymeric substances and its effect on algae
D. Lin, K. Zhou, Zhejiang University / Department of Environmental Science
Silver nanoparticles (AgNPs), as the most commercialized nanomaterial, are extensively used as bactericides or fungicides. As a consequence, AgNPs are increasingly released into the aquatic environment and potentially threaten plankton like algae. Exopolymeric substances (EPS) produced by algae may play an important role in the bio-nano interaction and nanotoxicity, which warrants to be investigated. We synthesized citrate- and PVP-stabilized AgNP suspensions (C-AgNPs and P-AgNPs, respectively), extracted EPS from a green alga (Chlorella.sp), investigated interactions between the AgNPs and the EPS, and specifically evaluated effects of the NP-EPS interaction on the algal accumulation and toxicity of the AgNPs. Results show that the algal EPS contained many active functional groups and strongly interacted with AgNPs as evidenced by the variation of UV and IR spectra, the increase in hydrodynamic sizes and zeta potentials, and the reduction in concentration of the released free Ag+ ions from the AgNPs in the presence of EPS. The EPS layer around algal cells slightly increased the algal adsorption of AgNPs but inhibited the cell internalization of AgNPs and alleviated the nanotoxicity. Compared with P-AgNPs, C-AgNPs had lower algal adsorption but higher Ag+ dissolution and cell internalization, and was therefore more toxic to the algae. This study highlights the importance of understanding the role of EPS in the bioaccumulation and toxicity of nanoparticles.

TU061
Impact of biosolid containing nanomaterials on a soil-plant-bacteria system
B. Collin, CEA-Aix Marseille Université / IBEBSBVMELEMIRE; E. Doelsch, CIRAD / UPR Recyclage et risque UMR SAS; M. Auffan, CEREGE / International Consortium for the Environmental Implications of Nanotechnology; N. Roche, Aix Marseille Université / MPTraitement des Eaux et des Déchets UMR; W. Achouak, UMR 7265 CNRS-CEA-Aix Marseille Univ / Laboratory of Microbial Ecology of the Rhizosphere Extreme Environments LEMiRE UMR CNRS CEA Aix Marseille University CEA Cadarache Saint Paul Lez Durance; C. Santaella, CNRS/CEA/Aix-Marseille Université / Bioscience and biotechnology Institute of Aix Marseille
Recent interest in the environmental fate and effects of manufactured CeO_2 nanomaterials (NMs) has stemmed from its expanded use for a variety of applications including fuel additives, catalytic converters, mechanical planarization media, coating and other uses.[1, 2] The majority of these NMs will end up in wastewater treatment plants (WWTP) where they will partition to sewage sludge during wastewater treatment, and ultimately re-enter the environment through the application of biosolids to agricultural soils.[3] Thus, soil may serve as a primary sink for NMs accumulation in the environment, in which NMs may enter food webs or cause direct toxicity to plants, microbial communities, or other soil organisms. Most of the available studies do not take into account environmental parameters such as the transformation of NMs in the environment or interactions between NMs and other contaminants. High concentration of trace elements (TEs) such as Cd, Pb, Zn, Ni are present in biosolids and can interact with NMs. With a large surface area for adsorption of TEs, NMs can facilitate the transport of TEs in soils[4] and modify their uptake by plant. This project aims to study the impact of Ce NMs on a soil-plant-microbe system using realistic exposure modes. Pristine CeO_2 NMs were first aged in a laboratory-scale activated sludge reactor during 5 weeks. The biosolid enriched NMs was then amended to a sandy loam soil (INRA's Couhins experimental farm, Bordeaux) at environmentally relevant

concentration: 1 mg Ce kg^{-1}. Canola plant (*Brassica napus*) was grown one month on this soil amended with the sludge without NMs or with biosolid enriched Ce NMs. Bulk Ce L_3-edge X-ray absorption spectroscopy (XAS) was used to study Ce speciation in the sludge before culture in order to evaluate the NPs transformation in the reactor. After the culture, elemental concentrations were measured in the plant parts by ICP-AES, and their distribution in roots by laser ablation ICP-MS. The first results indicate that the amendment of a biosolid polluted with CeO_2 NPs, performed at realistic concentration and after aging in a laboratory-cale reactor has an effect on the plant nutrients concentrations. Extensive analysis of elemental distribution in roots as well as effects on soil microbiota (microbial activities, bacterial community structure) are being performed in order to understand the impact of the enriched Ce biosolid and will be presented.

State of the science on poly- and perfluoroalkyl substances (PFASs) in the environment and humans (P)

TU062

A fast screening strategy for the analysis of poly- and perfluoroalkyl substances (PFASs) in solid matrices using laser diode thermal desorption coupled to high resolution mass spectrometry

G. Munoz, Universite de Montreal / UMR EPOC LPTC; S. VO DUY, University of Montreal / Chemistry; M. Desrosiers, CEAEQ; P. Labadie, H. Budzinski, CNRS; J. Liu, McGill University / Chesapeake Biological Laboratory; S. Sauve, Universite de Montreal

In recent years, concerns have arisen about the widespread environmental occurrence of poly- and perfluoroalkyl substances (PFASs) due to their potential for persistence, bioaccumulation and toxicity. Since the first specific analytical methods were published, significant advances have been made in the analysis of PFASs in complex matrices. However, conventional methods are relatively time-consuming to implement, requiring labor-intensive extraction and clean-up procedures, as well as a significant amount of sample material. The purpose of the present work was to develop a fast screening strategy for the analysis of legacy and newly-identified PFASs in solid matrices, using a reduced sample amount (< 200 mg) and a simple preparation procedure prior to instrumental analysis by laser diode thermal desorption atmospheric pressure chemical ionization (LDTD/APCI) coupled to high resolution mass spectrometry (Orbitrap-MS). The development of the analytical procedure was conducted with the help of experimental designs to identify optimum operating conditions, including the choice of a suitable extraction solvent, the amount of graphite used for sample clean-up, and LDTD instrumental settings. Following the addition of internal standards to the samples, an ultrasonic extraction step was performed using a small solvent amount (< 1 mL of methanol). For sample clean-up, graphite was then added (100 mg, batch) and the supernatant was recovered following centrifugation. 7 µL aliquots of sample were then analyzed by LDTD/APCI-Orbitrap-MS. The reduced sample preparation (no need of SPE manifold, no concentration step) and ultra-fast capability of the LDTD/APCI-Orbitrap-MS interface (acquisition time < 9 s per sample) imply that total analysis time (preparation + instrumental analysis) could be reduced to < 1 hour for 12 samples. The method was validated on fortified sediment and biota samples (i.e., assessment of detection limits, matrix effects, recovery, accuracy, and precision); when reference materials were available, method trueness was also evaluated. This allowed for the quantitative or semi-quantitative analysis of anionic, neutral and cationic PFASs in sediments and fish collected across Quebec at potentially-impacted sites (e.g., downstream from wastewater treatment plant effluents or aqueous film forming foam spills). Samples were also re-analyzed by LC/ESI-Orbitrap-MS, thus providing for a comparison with the newly-developed LDTD/APCI-Orbitrap-MS method.

TU063

Analysis of zwitterionic, cationic, and anionic fluoroalkylated surfactants in sediments by liquid chromatography polarity-switching electrospray ionization coupled to Orbitrap mass spectrometry

G. Munoz, Universite de Montreal / UMR EPOC LPTC; S. VO DUY, University of Montreal / Chemistry; P. Labadie, CNRS; F. Botta, INERIS; H. Budzinski, CNRS; F. Lestremau, INERIS; J. Liu, McGill University / Chesapeake Biological Laboratory; S. Sauve, Universite de Montreal

The environmental prevalence of poly- and perfluoroalkyl substances (PFASs) in aquatic environments has been well documented. To date, perfluoroalkyl acids (PFAAs) such as perfluoroalkyl carboxylates (PFCAs) and sulfonates (PFSAs) have garnered the most attention of PFAS monitoring surveys. However, recent reports indicate that a considerable portion of the total organic fluorine in environmental samples may be attributed to PFAA precursors and other unknown PFASs. Here, we describe a screening strategy for the identification and quantification of a wide range of PFASs in sediments. A total of 28 model PFAS analytes were selected for optimization and validation purposes, including 21 legacy PFASs and 7 novel cationic and zwitterionic PFASs. Instrumental analysis was conducted by ultra-high performance liquid chromatography coupled to a Q-Exactive Orbitrap through a polarity-switching ionization source, allowing simultaneous acquisition of negative and positive mode PFAS within a single run. The extraction/purification step was optimized to maintain a common preparation procedure for all PFASs at once, and adequate whole method recoveries were obtained (60–110 % for 28/28 model PFASs). Method validation included assessment of blank contamination, linearity, detection limits, matrix effects, recovery, accuracy and precision. The newly-developed method was subsequently applied to a selection of riverine or lacustrine sediment samples collected at large spatial scale in mainland France covering the six French Water Basins. In addition to the 28 model PFASs used for optimization and validation purposes, these samples were screened for more than 60 infrequently reported anionic, zwitterionic or cationic PFASs. Perfluorooctane sulfonate (PFOS) generally prevailed over other PFAAs (concentration range of PFOS: 0.084–23 ng g^{-1} dry weight). Fluorotelomer sulfonamide amines (FTAs) and fluorotelomer sulfonamide betaines (FTABs) were also particularly prevalent in these samples. Hot spots of zwitterionic/cationic PFAS (estimated $\Sigma PFAS^{+}$ = 8.9–27 ng g^{-1} dry weight) were associated with low-flow watercourses in the close vicinity of airports, suggesting the existence of firefighting activities at these sites involving aqueous film forming foam (AFFF) formulations. In the long run, FTAs and FTABs could degrade to more environmentally persistent PFASs such as PFAAs.

TU064

Determination of perfluoroalkyl substances in marine water and seawater sandworm Perinereis nuntia by liquid chromatography-tandem mass spectrometry

J.B. Sevilla-Nastor, National Institute for Environmental Studies; T. Sakurai, National Institute for Environmental Studies / Center for Environmental Risk Research

In this study, a high performance liquid chromatography-tandem mass spectrometry was used to determine 9 perfluoroalkyl substances in marine water and seawater sandworm *Perinereis nuntia*. The target PFASs were perfluoro-n-pentanoic acid (PFPeA), perfluoro-n-hexanoic acid (PFHxA), perfluoro-n-heptanoic acid (PFHpA), perfluoro-n-octanoic acid (PFOA), perfluoro-n-nonanoic acid (PFNA), perfluoro-n-decanoic acid (PFDA), potassium perfluoro-1-butanesulfonate (L-PFBS), sodium perfluoro-1-hexanesulfonate (L-PFHxS), and sodium perfluoro-1-octanesulfonate (L-PFOS). Marine water samples were filtered after collection and extracted and preconcentrated by solid phase extraction method. Sandworm *P. nuntia* was extracted using two methods – by manual extraction and by accelerated solvent extraction (ASE) and afterwards preconcentrated by the same SPE method that was used for marine water samples. Mass labelled PFASs (MPFAC-MXA) was used as the surrogate standard (SUR) added before the extraction of samples while M8PFOA and M8PFOS were used as the syringe spike internal standard to correct variations in both in extraction percentage and instrument response. Marine water samples extraction resulted to 57 to 115% method accuracy for all the target analytes. Manual extraction of sandworm was able to extract all PFASs (75 to 118%) while ASE extraction resulted in low method accuracy for short chain PFASs (i.e. PFPeA and PFHxA). Percent recoveries of SUR in marine water samples were between 52 to 72% (blank), 52 to 88% (1 ng), and 56 to 79% (10 ng). Manual extraction of sandworm resulted to 57 to 93% recovery of SUR compounds. ASE extraction gave higher recoveries of SUR compounds (62 to 92%). The developed methods can be applied to marine water and sandworm extraction to assure the quality of the data.

TU065

Development of Polar Organic Integrative Sampler for quantitative analysis of PFAS in surface waters

C. Simonnet-Laprade, UMR5805 EPOC; G. Munoz, Universite de Montreal / UMR EPOC LPTC; P. Labadie, CNRS; H. Budzinski, University of Bordeaux / UMR EPOC LPTC

Since the beggining of the 1990s, the development of passive samplers to analyze organic micropollutants in surface waters has been the subject of a large number of studies. They offer a complement to grab sampling, allowing for a better qualitative and quantititative analysis of a wide variety of contaminants. For instance, the Polar Organic Chemical Integrative Sampler (POCIS) has gained particular attention in recent years for the analysis of pesticides or pharmaceuticals. However, the application of this tool to poly- and perfluoroalkyl substances (PFAS) has been rarely reported, in spite of the ubiquitous character of these chemicals in aquatic environments. In this context, the present work consists in the development of a POCIS-like sampler allowing for the PFAS analysis in water, through a two-step approach. First of all, the selection of a suitable configuration was realised under controlled conditions for 12 PFAS (9 carboxylates and 3 sulfonates). Four configurations based on Strata-XAW or Oasis HLB sorbents enclosed between Nylon or PES membranes were compared. The second step consisted in the *in situ* calibration of selected configurations with a two-fold objective: to extend the list of targeted PFAS and to evaluate the environmental parameters that could influence the sampling rates Rs (necessary for quantitative analysis). The realibility of the tools for the quantitative analysis was evaluted in a last *in situ* experiment (7 days of exposure). The first experiment showed that only the Strata X-AW sorbent accumulated the 12 target compounds (in agreement with previsous report, PFBA was not accumulated by the HLB phase). The highest Rs were obtained with the Strata X-AW / PES configuration (Rs = 0.02-0.45 L/d). However, a lag-effect was observed with PES membranes because of the PFAS affinity for this material. Better linearity of PFAS accumulation (and, as a consequence, better quantitative analysis) was observed for long-chain carboxylates and sulfonates with the Strata X-AW / Nylon configuration (Rs = 0.08-0.29 L/d). The latter configuration was therefore elected, and subsequently calibrated in a periurban river near Bordeaux. 22 PFAS were dectected in grab and passive samplers. Sampling rates, similar to those obtained in a laboratory**,** ranged from 0.07 to 0.42 L/d and the linearity period was in the range 2.5-15 days. In situ assessment showed good agreement between concentrations obtained with grab and passive samplers.

TU066
Multianalyte profiling of per- and polyfluoroalkyl substances (PFASs) in liquid commercial products
P. Favreau, STEB / Department of Environment Transport and Agriculture; C. Poncioni-Rothlisberger, Geneva State / Department of Environment Transport and Agriculture; B. Place, National Institute of Standards and Technology; H. Bellomie, A. Weber, J. Tremp, Swiss Federal Office for the Environment; J. Field, Oregon State University / Department of Environmental and Molecular Toxicology; M. Kohler, Geneva State / Department of Environment Transport and Agriculture
The specific chemical properties of per- and polyfluoroalkyl substances (PFASs) make them widespread for use in a number of industrial and commercial products. For instance, PFAS are known to occur in consumer products and are added to confer water and oil-repellency characteristics (e.g. waterproof, anti-stain) and to reduce surface tension in aqueous-film forming foams (AFFF). Some perfluoroalkyl acids (e.g., carboxylates and sulfonates), are known to cause significant human and negative environmental impact. Our current knowledge on the occurrence and content of specific PFAS in commercial products remains very scarce due to limited information available, thus impeding any precise assessment of human exposure and environmental release upon use. This study aimed at collecting 194 samples in Switzerland, and included a wide variety of liquid products likely to contain PFASs. Liquids tested included: impregnating agents, lubricants, cleansers, polishes, fire-fighting foams and other industrial products. By means of LC- and GC-MS/MS analytical techniques, a total of 24 different PFASs comprised of over 41 targeted compounds were detected and quantified in 55% of 194 samples. PFAS quantification and compound profiling was found to be consumer-product specific. PFASs were mainly found in AFFF (90% occurrence) and impregnating agents (60% occurrence) with more than 100 ppm of targeted PFASs in both cases. Mainly ionic (carboxylates, sulfonates) and neutral (fluorotelomer alcohols, acrylates) species were detected for AFFF and impregnating agents. Further investigation by Fast Atom Bombardment Mass Spectrometry (FAB-MS) on a set of AFFF samples allowed the characterization of 8 additional PFAS classes as major components in commercial AFFF formulations. Altogether, these results demonstrate the significant presence of numerous known and emerging PFASs in specific commercial products, which provide a source of further human exposure and environmental release.

TU067
Perfluorinated compounds (PFASs) in Northern Spain municipal solid waste landfill leachates
S. GOMEZ-LAVIN, University of Cantabria VAT Nº QC / Chemical and Biomolecular Engineering; I. FUERTES, M. ELIZALDE, University of the Basque country UPVEHU / Analytical Chemistry; A. URTIAGA, University of Cantabria VAT Nº QC / Chemical and Biomolecular Engineering
Per- and polyfluorinated compounds (PFASs) are recognized as chemicals of environmental concern due to their ubiquitous presence in the environment. PFASs are highly persistent and some are bioaccumulative. They are used as surfactants, coatings and fire-fighting agents, as well as chemical components of an extensive array of consumer products that are ultimately disposed of in waste and wastewater systems. Given the potential for landfills to act as important environmental point sources of PFASs, the characterization of the PFASs present in landfill leachates is of paramount importance to provide details on loadings and sources to the environment. The few available data on PFASs occurrence in leachates correspond to landfills from North America, Europe and China. Recent surveys in China have revealed that leachates can contain levels of PFASs as high as 292000 ng/L. This work aims to study for the first time the occurrence of PFASs in leachate samples from municipal solid waste landfills in Northern Spain. The levels of eleven perfluoroalkylcarboxylic acids (PFCAs) and five perfluoroalkylsulfonates (PFSAs) have been assessed by high performance liquid chromatography and tandem mass spectrometry (HPLC-MS/MS) in four raw leachates and two treated leachates, ranging the total PFASs concentration from 562 ng/L to 2921 ng/L. PFASs concentrations were higher in treated leachates compared to their respective raw leachates, what suggests a possible degradation of PFASs precursors during treatment and the persistence of PFASs against biodegradation. Compounds like PFHpA, PFDA and L-PFBS were measaured in higher concentrations after application of the leachate treatments (biological and ultrafiltration). However, concentration of PFOA and L-PFOS diminished after the application of the leachate treatments. Overall, PFCAs accounted for the majority of PFASs, compared to PFSAs. Furthermore, short chain PFASs were detected with higher frequency, which could be caused by the production shift to products containing shorter-chain PFASs. PFOA was the pedominant compound in 3 of the samples (accounted 51-84%), L-PFBS was the pedominant PFAS in 2 samples and PFHxA was the most abundant in one sample (26%).

TU068
Comprehensive Monitoring of PFASs Precursors in Industrial and Municipal Wastewater Treatment Plants
C. Gremmel, T. Frömel, I. Dimzon, Hochschule Fresenius, University of Applied Sciences; P. de Voogt, University of Amsterdam / IBED; T.P. Knepper, Hochschule Fresenius, University of Applied Sciences
Perfluoroalkyl and polyfluoroalkyl substances (PFASs) are anthropogenic and broadly distributed via aqueous compartments around the world. Wastewater treatment plants (WWTPs) have been identified as a significant pathway for the introduction of PFASs to natural waters. Several studies, e.g. from 2006, 2010 and 2011 showed higher concentrations of PFASs analysed in the effluent of WWTP compared to the corresponding influent [1-3]. One reason for this might be the biotransformation of precursor substances, which were converted into known and analysed PFASs. Precursor substances can be fluorotelomer compounds, such as fluorotelomer alcohols (FTOHs), which have been shown to degrade to perfluoroalkyl carboxylic acids (PFCAs). Therefore, a comprehensive study was carried out in the framework of a project funded by the German Environmental Agency, sampling six municipal and industrial wastewater treatment plants located in Europe. A total of 65 PFASs were monitored using HPLC-ESI-MS/MS and GC-EI-MS methods. For wastewater treatment plants, eight influent samples and four effluent samples were taken over a period of four weeks. Additionally, eight corresponding air samples above the influent were taken in order to verify the presence of volatile PFASs as well as four grab sludge samples to account for adsorbable PFASs. Various findings of both, precursors, biotransformation intermediates and stable PFASs will be presented and discussed.

Black guillemot sheds light on local pollution in the Arctic: Levels, profiles and effects of PFAS
N. Eckbo, Institutt for biovitenskap; D. Herzke, Norwegian Institute for Air Research NILU; A. Haarr, University of Oslo / Department of Biosciences; K. Hylland, University of Oslo / Biosciences; N.A. Warner, NILU - Norwegian Institute for Air Research / Environmental Chemistry; G. Gabrielsen, Norwegian Polar Research Institute; K. Borga, Department of Bioscences, University of Oslo / Department of Biosciences
The auk Black guillemot (Cepphus grylle) is a year-round resident species at Svalbard. Since it does not migrate south during the winter season, we can expect that all contaminant uptake comes from the local diet. Hence, the Black guillemot may help shed light on local pollution. Over the past 18 years, levels of legacy contaminants have decreased in another auk, Brünnich guillemot (Uria lomvia), which is monitored at Svalbard and Jan Mayen (MOSJ). However, the Arctic is experiencing an increasing input of emerging contaminants such as perfluorinated substances (PFAS); The Brünnich guillemots restrict themselves to the northern hemisphere but migrate during winter, spreading across the North Atlantic; Iceland, Faroe Island, Greenland and Canada where they might be exposed to different levels and cocktails of contaminants. As a result, we know little of the levels and profiles of legacy and emerging contaminants in species that spend their whole year feeding in the same area, such as the Black guillemot. The Black guillemot is a diving seabird foraging on small fish and crustaceans, closely related to the Brünnich guillemot, and hence resembling each other both ecologically and physiologically. Therefore, by comparing our results with available MOSJ data for Brünnich guillemot, we expect similar levels, but different profiles due to differences in foraging areas and contaminant uptake throughout the year. In addition, there is little knowledge about how the seabirds are affected by the contaminants regarding both concentration levels and chemical mixtures. This knowledge gap will be investigated in this study, through the measurement of DNA damage using the comet assay in Arctic seabirds in relation to contaminant body burdens. Contaminants may influence several steps in the antioxidative defense system and thus lead to increased oxidative stress and possible damage to DNA. Measured DNA damage occurring in Black guillemots will be used to establish a baseline, linking DNA damage to PFAS levels in the same individuals. Blood was collected from Black guillemots (N=15) in Kongsfjorden, Svalbard, summer 2015, and were analysed for PFAS as well as legacy contaminants, diet signatures and DNA damage, using the comet assay. Our questions were: 1) How does PFAS levels and profiles in a resident species differ from migrating species at comparable trophic levels? 2) How are contaminants levels and profiles linked to the amount of DNA damage observed in the Black guillemot?

TU070
Perfluorinated compounds in water, sediment and wild bird eggs from the Orange-Senque River basin, South Africa
C. Swiegelaar, L.P. Quinn, D. Prevoo-Franzsen, NMISA / Organic and BioAnalysis; H. Bouwman, North-West University / Unit for Environmental Sciences and Management
Currently, data concerning Perfluorinated Compounds (PFCs) is limited for the

South African environment. This study focussed on the analysis of selected PFCs from multiple environmental matrices in the Orange-Senqu River basin, one of the largest river systems in South Africa. Extraction and clean-up methods employed, varied for each matrix. Abiotic samples were extracted using sodium hydroxide followed by weak anion exchange solid phase extraction (SPE). Biotic samples were extracted using methanol in combination with dispersive activated carbon SPE clean-up. Thereafter, the extracts were analysed using liquid chromatography tandem mass spectrometry (LC-MS/MS). The mean recoveries for PFCs varied between 18 – 105% for water; 33 – 122% for sediment, soil and tailings dam waste; and between 45 – 137% from bird eggs. Perfluoroheptanoic acid (PFHpA) and perfluorohexanesulfonic acid (PFHxS) were not detected. Only 8% of water samples analysed had quantifiable PFCs, while soil, sediment, and tailing matrixes also showed a low frequency of occurrence with only 24% of samples containing PFCs. Measurable concentrations within the aquatic environment were expeted where the wild bird eggs were collected. Ninety percent of the bird eggs analysed had quantifiable concentrations of PFCs. PFOS had the highest prevalence, followed by perfluorodecanoic acid (PFDA) and perfluorononanoic acid (PFNA). The concentrations of PFOS in eggs of the same species from the same site were quite variable, probably due to their wide feeding ranges. This variability was further investigated by ensuring the validity of analytical identification, as well as looking at unique environmental exposure routes. PFOS identification was confirmed by retention time, mass transition, and isotope modelling against an authentic PFOS standard. Acknowledgements: Financial assistance was provided by the Department of Trade and Industry, the United Nations Office for Project Services and the National Research Foundation, South Africa.

TU071
PERFLUOROALKYL SUBSTANCES (PFASs) IN REMOTE HIGH ALTITUDE AREAS AROUND THE GLOBE
A. Dreyer, Eurofins GfA GmbH / Air Monitoring; F. Neugebauer, Eurofins GfA Lab Service GmbH / Reasearch Development; M. Wang, K. Brigden, I. Labunska, D. Santillo, Greenpeace Research Laboratories; M. Santen, Greenpeace
Perfluorinated alkyl substances (PFASs) are compounds of environmental concern. Of the numerous PFAS investigated in environmental samples, perfluorooctane sulfonate (PFOS) is listed as persistent organic pollutant and recently the German Environment Agency submitted a proposal at ECHA to restrict perfluorooctanoate (PFOA). In the past, several perfluorinated acids have been detected in snow or firn of high altitude regions in Central Europe. In the present study, we investigated the presence of these compounds in snow and water samples at altitudes up to 5000 m a.s.l. at 8 remote sites. These were located in South America, Asia, Northern and Central Europe. Snow and lake water samples were taken in duplicate and one field blank was taken per site. Whenever the amount of melted snow was too small, samples were combined. PFASs were detected at all sites in water and/or snow samples. Highest PFAS snow concentrations were observed in Slovakia (High Tatras) and Italy (Monti Sibillini) with perfluorononate (PFNA) being the compound which contributed the most. Lowest concentrations were observed in China. Highest PFAS concentrations in lake water samples were observed in Switzerland (Macun Lakes) followed by Russia (Altai) and Slovakia (High Tatras) usually with PFOA contributing the most. The occurrence of PFASs at high altitude lake and snow samples demonstrates the ubiquitous distribution of these compounds and indicate their atmospheric transport to remote regions, probably by degradation of atmospherically transported volatile precursors.

TU072
Accumulation and temporal trends of PFCs in finless porpoises (Neophocaena asiaeorientalis) collected from Korean coastal waters between 2003 and 2010
y. jeong, A. Shen, Hanyang University; J. Lim, Hanyang Univeristy; J. Lee, S. Lee, Hanyang University; Y. An, Cetacean Research Institute (CRI), NFRDI; H. Moon, Hanyang University / Marine Sciences and Convergent Technology
Perfluorinated compounds (PFCs) are ubiquitous contaminants in marine environmental compartments such as seawater, sediment, and biota. However, limited information is currently available on temporal trends of perfluorinated compounds (PFCs) in marine mammals from Korean coastal waters. In our study, accumulation and temporal trend of perfluorinated compounds (PFCs) were examined in liver samples of finless porpoise (*Neophocaena asiaeorientalis*) collected from Korean coastal waters between 2003 and 2010. Total concentration of PFCs (∑PFC; sum of 3 sulfonates, and 12 carboxylates) ranged from 123 to 1322 ng/g wet weight (ww) (median: 447 ng/g ww) for 2003 (n=27), and 245 to 3690 ng/g ww (median: 840 ng/g ww) for 2010 (n=77). In both years, PFUnDA (C_{11}) showed the highest contribution, followed by PFOS (C_8) contributed collectively over 70% of the ∑PFC concentrations. Other longer-chain carboxylates such as PFDoDA (C_{12}), and PFTrDA (C_{13}) also had relatively higher contributions than other PFCs. To investigate age-, and sex-dependent accumulation pattern, specimens in 2003, and 2010 were divided into 4 groups (immature male/female, and mature male/female). The median concentrations of PFCs were higher in immature female followed by immature male, mature male, and mature female in both years. In 2010 male specimens, as body length increases, the concentration of PFCs showed decreasing trend ($p < 0.05$), suggesting biodilution effect of PFCs. The ∑PFC concentrations of mature females in both years were lower than immature male/female, suggesting the excrection of PFCs via placental transfer and lactation. Compared to 2003, the ∑PFCs concentrations were significantly increased in 2010 ($p < 0.0001$). Among major compounds (which contributes >5% to ∑PFC concentration), PFOS (182%) showed the highest increasing rates than other compounds (PFUnDA: 73%; PFDoDA: 82%; PFTrDA: 40%). Our result suggests that a certain time would be needed for phase-out of PFCs in marine mammals due to the on-going use of products containing PFCs.

TU073
Particle-Induced Gamma-ray Emission (PIGE) as a Novel Screening Method for PFASs in Groundwater
G.F. Peaslee, Hope College / Chemsitry; D.F. Lunderberg, Hope College / Chemistry Dept; E. Ritter, UMP Analytical LLC; W. DiGuiseppi, CH2M Inc; D. Bogdan, AECOM; J. Field, Oregon State University / Department of Environmental and Molecular Toxicology; K. Barzen-Hanson, Oregon State University
Because of the environmental persistence of per- and polyfluoroalkyl substances (PFASs), their ability to bioaccumulate, and their suspected human toxicity, new methods to identify these chemicals at trace levels in groundwater are needed. Particle induced gamma-ray emission (PIGE) spectroscopy is an established ion beam analysis technique that has been used to quantitatively measure light elements, including fluorine, in diverse target materials. An *ex-vacuo* PIGE method has been developed and is shown to be an effective and sensitive tool to determine the total organofluorine content in groundwater. Solutions of various chainlength perfluorinated acids and sulfonates were extracted onto the surface of a weak anion exchange solid-phase extraction (SPE) cartridge. This pre-concentration method was sufficient to use realistic volumes (40 - 80 mL) of distilled water to measure total fluorine. The total fluorine measured on these cartridges by PIGE correlates well with the initial PFAS concentrations for a broad range of anionic PFASs. Subsequent experiments with actual contaminated groundwater from two US sites further demonstrate PIGE to be an inexpensive, rapid, and non-destructive method for total fluorine analysis. Spike and recovery tests have been performed as well as a post-extraction method to remove fluoride ions from the cartridges. Thie novel spectroscopic method for detection of PFAS can be adapted to detect environmentally-relevant PFAS concentrations in groundwater and may be very suitable as a pre-screening method to determine the presence or absence of PFASs in groundwater samples.

What do we know about indirect exposure to PFOS? In vitro metabolism of MeFOSE and MeFOSA
A. Miralles-Marco, University of Birmingham / School of Geography Earth Environmental Sciences; L. Lucattini, A.M. Ballesteros-Gómez, Vrije Universiteit Amsterdam / Institute for Environmental Studies IVM; S.J. Harrad, The University of Birmingham / Division of Environmental Health and Risk Management College of Life and Environmental Sciences; P.E. Leonards, Vrije Universiteit Amsterdam / Institute for Environmental Studies
Perfluorooctane sulfonate (PFOS) is a widely known Persistent Organic Pollutant (POP) with an extensive historical use, until its restriction in the early 2000s. Due to its proven toxicity and health concerns it was incorporated in the Stockholm Convention on POPs in 2009. After the phase out by the principal manufacturer (3M) in 2000-2002, trends in direct exposure to PFOS have been reported to decline. However, the indirect exposure through PFOS-precursors that are metabolized to PFOS has been suggested in recent literature. This PFOS indirect exposure could be an increasingly important contribution to the levels of PFOS in biological samples: estimates derived from modelling studies range current exposure from these PFOS-precursor compounds between 10% and 40% of total PFOS body burdens. Such PFOS-precursor compounds include perfluorooctane sulfonamides (FOSAs) and sulfonamidoethanols (FOSEs), which historically were synthesized to produce polymeric materials and phosphate esters, for their later use on surface coatings for textiles and paper products. However, there are still several uncertainties associated with these estimates and metabolism of not all PFOS precursors have been investigated so far. So, further *in silico*, *in vitro* and *in vivo* studies of these compounds are strongly required, as they would render the margin of safety between the current exposure limits and estimates of external exposure to PFOS alone. In the current work, the *in silico* and *in vitro* metabolism with human liver microsomes (HLM) and cytosol (HLCyt) of two of these “PFOS-precursors” ((N-methylperfluoro-1-octanesulfonamido)-ethanol (MeFOSE) and N-methylperfluoro-1-octanesulfonamide (MeFOSA)) were investigated. Results show at least 4 expected metabolites for MeFOSE and 5 for MeFOSA (eg. PFOS, FOSA, hydroxylated metabolites, break-down products and conjugations).

The remediation of PFAS contaminated airport soils
S. Hale, NGI; . HÃis‿ter, G. Slinde, Norwegian Geotechnical Institute; H. Arp, NGI / Environmental Engineering; G.D. Breedveld, NGI / Department of Environmental Engineering; P. Cappelen, E. Wade, Norwegian Geotechnical

Institute; B. Straith, K. Moe, M. Jartun, Oslo Lufthavn AS
AFFF has been used historically at Norwegian airports and as such has resulted in contamination of ground water and soils with a multitude of per- and polyfluoroalkyl substances. The behaviour of PFASs in the unsaturated soil zone and the way in which this affects contamination of underlying groundwater is relatively unknown. In order to suggest suitable methods of remediation that comply with environmental legislations it is important to obtain an understanding of this behaviour. In Norway very low target values for the concentration of PFOS that are permitted in water and soil drive remediation efforts. Cleaning up to such low concentrations is technologically, logistically and chemically challenging. Here we present a feasibility study for the remediation of a soil from a Norwegian airport and contaminated with PFOS. Soil samples were taken from a currently used firefighting training facility and the concentration of a variety of PFASs was quantified. Concentrations of PFOS ranged from 6.4 ∃g/kg up to 2600 □g/kg and all of the soil samples were sandy in nature. Lab experiments were carried out to investigate leachability using a shaking test. The standard shaking test involves mixing the soil with water at a L:S ratio of 10 and revealed that the leachability of PFOS was up to 100 % of the total concentration. For both the total concentrations of PFOS and the leaching there were no clear trends with soil properties (K_D, organic matter content, Ca content, Cl content, pH, Mn content, Fe content or SO4 content). Soil-water partitioning coefficients were calculated and were low for these samples (2 to 50 L/kg). Remediation trials were tested in the lab for a possible field clean-up effort and they consisted of soil washing to remove a great deal of PFOS and stabilisation to immobilize the remaining PFOS. Activated carbon, a clay and an organic matter rich compost soil were tested as the sorbents for stabilisation. Soil washing involves the addition of a vast quantity of water and a separation of different soil fractions. The presentation will show the results of these trials which will be instrumental in order to suggest the most feasible site remediation options in collaboration with the Norwegian Airport Authority and the Norwegian Environment Agency.

Performance and hazard assessment of fluorinated and non-fluorinated state-of-the-art DWR-polymers
S. Schellenberger, Stockholm University / Department of Applied Environmental Science ACES; H. Holmquist; I.v. Veen, Institute for Environmental Studies (IVM) VU University Amsterdam / Chemistry and Biology; G.M. Peters, Chalmers University of Technology / Department of Chemistry and Chemical Engineering; P.E. Leonards, Vrije Universiteit Amsterdam / Institute for Environmental Studies; P. Gillgard, Swerea IVF AB; I. Cousins, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES
Durable water repellent (DWR) impregnation is applied in textile finishing to impart water and, depending on impregnation chemicals, oil and stain resistance to textiles. Following the phase-out of the most effective and predominating DWR-technology based on long-chain per- and polyfluoroalkyl substances (PFASs), the textile industry had to find suitable alternatives. This phase-out has resulted in a market where both fluorinated and non-fluorinated DWRs are available, dividable into three broad groups: short chain PFAS-based, silicone-based and hydrocarbon-based polymers. During our research in the SUPFES (Substitution of prioritised poly- and perfluorinated chemicals to eliminate diffuse sources) project, the alternative DWRs were assessed with regards to: (i) their structural properties and connected performance, (ii) loss and degradation processes resulting in diffuse environmental emissions, and (iii) hazard profile for selected emitted substances. We worked with DWR-chemistry and raw material producers to appropriately treat two commercially relevant types of fabrics with the DWR alternative chemistries (fluorinated and non-fluorinated). We compared the performance of the treated fabrics developed in the project by testing the following properties using industrial standardised methods: general properties, physical properties, DWR properties and stabilities of properties considering relevant stress- parameters. We demonstrated that non-fluorinated alternatives can have a competitive water repellency in comparison to short-chain PFAS substitutes, but that they lack oil repellence. We further estimated possible loss mechanisms for impurities and/or degradation products from DWR-treated fabrics and conducted a hazard assessment for relevant chemicals based on data available in the literature. Our hazard ranking suggests that hydrocarbon-based polymers are the most environmentally benign, followed by silicone- and fluorocarbon-based polymers. Future work will include risk assessment and life cycle assessments (LCA) to estimate long-term advantages and disadvantages of the different DWR-technologies.

Dietary exposure to PFOS and PFOS precursors of Norwegian population
A. Miralles-Marco, University of Birmingham / School of Geography Earth Environmental Sciences; S. Poothong, Norwegian Institute of Public Health; S.J. Harrad, The University of Birmingham / Division of Environmental Health and Risk Management College of Life and Environmental Sciences; J.A. Padilla, L.S. Haug, E. Papadopoulou, Norwegian Institute of Public Health
Perfluorooctane sulfonate (PFOS) has been a widely used organic pollutant until its restriction in the early 2000s. It was listed in the Stockholm Convention on Persistent Organic Pollutants (POPs) in 2009. Several studies have been published reporting environmental or dietary exposure data, biomonitoring levels and health concerns. Notwithstanding reports that absolute levels of PFOS in human biomonitoring studies are declining; recent published studies of environmental, dietary exposure data and biomonitoring levels, highlight that uncertainties in terms of exposure and metabolism still remain, as the levels are decreasing slower than predictions suggest. To illustrate, indirect exposure to PFOS-precursor compounds followed by *in vivo* metabolism to PFOS has been highlighted as a potentially important source of current levels of PFOS present in biological samples. Current modelling studies estimate such PFOS-precursor exposure after the 3M phase out contributes between 10 and 40% of total PFOS body burdens. This evidence is supported by a small number of *in vivo* and *in vitro* studies, which report conversion rates up to 20% (e.g. EtFOSE in long term exposed rats). As a consequence of this evidence, further study of the external exposure to these PFOS-precursors substances is required. In an effort to enhance understanding of why levels of PFOS are not decreasing as expected, this study reports dietary exposure to the following PFOS-precursor compounds: sulfonamides (FOSAs), sulfonamidoethanols (FOSEs) and sulfonamide alcohols (FOSAAs). This is achieved via analysis of 24 h duplicate diet samples from 61 Norwegian adults in 2014 These data will be linked to food questionnaires, to help identify which groups of food are the main contributors to dietary exposure to these compounds for this cohort.

Alternative approaches to animal testing for ecotoxicity assessments (P)

Whole effluent testing (also called Direct Toxicity Assessment) remains a critical long-term assessment tool for aquatic environmental protection. Use of animal alternative approaches for wastewater testing is expected to increase as more regulatory authorities routinely require fish and invertebrate tests for effluent assessments or as dischargers seek means to reduce overall animal (fish) use. To address the current state of the science associated with the use of alternative (3R) methods in effluent testing and assessment, a survey was conducted to identify the numerous and varied testing strategies to assess the potential environmental impact of effluents. This survey was aimed at summarizing the breadth of effluent testing approaches that are currently used in various regions and countries. Several questions were asked about the types of regulatory programs used to control the discharge of toxic chemicals, and at what level wastewater discharges are regulated. Specific information on what testing methods and species are used was requested, as well as whether non-animal alternative methodologies are used or considered for effluent/wastewater biological assessments. Finally, several questions inquired about the type of treatment for the various types of dischargers and what, if any, regulatory requirements or regulatory monitoring exists to regulate toxics wastewater. This survey provides the baseline knowledge to assess the role of biological testing for wastewater streams and identify opportunities to use novel strategies in an integrated manner to both optimize testing approaches and reduce reliance on animal tests on a global scale. The results of the survey were one of the cornerstones of the International Workshop titled "Concepts, Tools, and Strategies for Effluent Testing" facilitated by the ILSI Health and Environmental Sciences Institute (HESI) Animal Alternatives in Environmental Risk Assessment Technical Committee. *Disclaimer: The views, conclusions and recommendations expressed in this article are those of the author and do not necessarily represent views or policies of Environment Canada or the US Environmental Protection Agency*

TU079
How the integration of sub-lethal criteria and of genotoxicity assessment can improve the Fish Embryo Toxicity test sensitivity

A. Wigh; S. BONY, INRA - CNRS / UMR LEHNA USC INRA IGH ENTPE; H. Terrisse, Université de Lyon / UMR CNRS LBBE and VetAgro Sup Campus Vétérinaire de Lyon; M. Delignette-Muller, VetAgro Sup / Laboratory of Biometry and Evolutionnary Biology; A. Gonzalez-Ospina, Degremont / Degremont; B. Domenjoud, SUEZ Treatment solutions; A. DEVAUX, INRA-CNRS / UMR LEHNA USC INRA IGH ENTPE
The Fish Embryo Toxicity (FET) test using zebrafish (*Danio rerio*) is commonly used as an alternative to determine acute toxicity of chemicals or environmental samples on adult fish. In the FET, only lethality is used to calculate a LC_{50} value after 96h of exposure. This work aims to integrate to the FET 9 sub-lethal events: abnormal eye development and/or pigmentation, presence of edema, blood circulation defect, malformations (head, tail; heart, spine and yolk sac) as well as the DNA damage level in cells isolated from 96h exposed embryos. The objective is to improve the sensitivity of the test and to achieve a more accurate toxicity evaluation of samples. This approach was first tested with a model toxicant: 3.4-dichloroaniline (3.4-DCA) and was then used to assess the residual toxicity of two wastewater effluents (hospital and urban mixture) treated by conventional activated sludge alone (CAS), or followed by tertiary ozonation (CAS+O_3) with an ozone dose of 5 mg O_3/L. Considering dead embryo or alive embryo with at least one of the 9 sub-lethal criteria equally as “affected embryo”, an EC_{50} value of 1.65 mg/L was estimated after 3.4-DCA exposure, when the FET LC_{50} was 3.75 mg/L. In a second approach, the distribution of the number of sub-lethal plus the lethality criteria (0-10) among 60 embryos per concentration was represented as a score. The number of abnormal embryos and the number of sub-lethal criteria recorded per embryo increase with 3.4-DCA concentration. Considering only the mortality endpoint, a significant difference compared to the control was found at 3.7 mg/L, while through the integration of sub-lethal endpoints a significant difference compared to the control was already observed at 0.7 mg/L of 3.4-DCA (Wilcoxon rank sum test). Moreover, a significant increase in the DNA damage level (Comet assay) was found in embryonic cells from the lowest tested 3.4-DCA concentration (0.7 mg/L). Embryo mortality in CAS+O_3 effluent was not statistically different compared to the control but a significant increase in developmental abnormalities was observed. Additionally, a residual genotoxicity was shown in this WWTP effluent despite tertiary ozonation. With the integration in the FET of several sub-lethal criteria and of a genotoxicity assessment, an improved sensitivity of the bioassay was achieved that allowed to reveal a residual toxicity in a treated wastewater characterized by a complex organic chemical mixture at low concentration.

TU080

Environmental Effects Monitoring as a tool for Effluent Testing

M.E. McMaster, Environment Canada / Water and Science Technology Directorate Aquatic Contaminants Research Division; J. Parrott, Environment Canada / Water Science and Technology Directorate; M. Hewitt, Environment Canada / National Water Research Institute; K.R. Munkittrick, COSIA
As part of the HESI Animal Alternatives in Environmental Risk Assessment Technical Committee's "Concepts, Tools, and Strategies for Effluent Testing: An International Workshop" various Case studies were presented on methods used in different countries to monitor effluent. In Canada starting in 1992 an Environmental Effects Monitoring (EEM) program was developed for the Pulp and Paper industry. This program requires each discharger to monitor fish and benthic invertebrates both upstream and downstream of its discharge to evaluate effects it may have on the receiving environment. The Government of Canada than uses this information Nationally to determine whether its existing discharge limits for the industry are protective of all receiving environments. The program is cyclical in nature with upcoming cycles dependant on results of the previous cycle on a mill specific basis. Effects in a receiving environment are confirmed in the next cycle, following confirmation the extent and magnitude of the effects are evaluated. Once effects are documented, investigation of cause and solution are then implemented. The pulp and paper program is now entering its 8th cycle and has implemented solutions to some of the effects documented. The EEM field program is then used to confirm improvements in the receiver following implementation. The program was adapted for use at all metal mines in Canada in 2002 and has considered implementation for municipal waste water discharges. It is also the same methodology implemented for the fish program in the Alberta Oil Sands Area. This program has been used or applied in a number of countries including Chile, Brazil and Uruguay. Discussions will include how this tool has been used for effluent testing in Canada and if it may be used as an alternative for laboratory effluent testing in certain cases.

TU081

Implementation of ecotoxicological tests using freshwater planarians: Choice of cultivation medium by using the fecundity mean index as viability marker

A.R. Ribeiro, University Duisburg-Essen; N. Ruchter, University of Duisburg-Essen; B. Sures, University of Duisburg Essen / Aquatic Ecology; T.C. Schmidt, University of Duisburg-Essen
Freshwater planarians have been successfully used in several ecotoxicological methods. This invertebrate can respond to environmental contaminants from molecular to behavioral level. However, there are no standard guidelines for bioassays or laboratorial cultivation. Consequently, there are problems in cultivation and in results replication and interpretation. This work aimed to use the reproductive success of two planarian species in laboratory as deciding factor for the cultivation medium’s choice. Sexual specimens of *Girardia tigrina* (Gt, n=45) and *Schmidtea mediterranea* (Sm, n=20) were donated by the Max Planck Institute for Molecular Biomedicine (Münster, Germany). During the following four weeks of adaptation, all animals were maintained in glass vessels containing the donator’s medium (Münster’s tap water plus Montjuic salts (MJ) – 1.6 mM NaCl, 1 mM $CaCl_2$, 1 mM $MgSO_4$, 0.1 mM $MgCl_2$, 0.1 KCl and 1.2 mM $NaHCO_3$, pH 7), but any cocoons were produced. After that, animals were split in 10 experimental groups according to specie (Gt and Sm) and cultivation medium (Essen’s tap water plus and without MJ, commercial spring water plus and without MJ and ultrapure water plus MJ). The population density was 0.025 org/ml. During the five testing weeks all vessels were held in darkness under controlled room temperature (17.9 ± 0.9°C). After weekly feeding with bovine liver, the medium were completely renewed. To determine the mean fecundity index (FC) the total number of cocoons collected in each experimental group per week was divided by the respective number of planarians. Then, the weekly FC’s of each group were compared using analysis of variance (ANOVA) followed by Tukey test, at significance level $p \leq 0.05$. As a result, the higher and statistically significant FC values were 0.59 ± 0.4 (Gt) and 0.32 ± 0.4 (Sm) obtained in the groups just in tap water. The other groups presented lower FC values ranging from 0 to 0.3. In short, all observed FC’s are still lower than the expected for planarians. As an example, literature indicates a FC > 1 for Gt in healthy laboratorial conditions. However, the fecundity mean index has been shown as a great marker to assess planarian viability in laboratory.

Commission - Joint Research Centre / IHCP System Toxicology Unit EURL ECVAM; T.J. Norberg-King, U.S. EPA / NHEERLMidContinent Ecology Division; H. Sanderson, Aarhus University Department of Environmental Science / Department of Enviromental Sciences; R.M. Sternberg, U. S. EPA / Environmental Fate and Effects Division; J.G. Suski, U.S. Environmental Protection Agency / Safer Choice Program; P.W. Wilson, Sanofi U.S., Inc. / Health Safety and Environment
There are various structure-based classification schemes to categorize chemicals based on mode of action (MOA) which have been applied for both eco- and human health toxicology. With increasing calls to assess thousands of chemicals, some of which have little available information other than structure, clearly understanding how each of these MOA schemes was devised, what information they are based on, and the limitations of each approach is critical. Several groups are developing low-tier methods to more easily classify or assess chemicals, using approaches such as the ecological threshold of concern (eco-TTC) and chemical-activity. Evaluation of these approaches and determination of their domain of applicability is partly dependent on the MOA classification that is used. The most commonly used MOA classification schemes for ecotoxicology include Verhaar and Russom (included in ASTER), both of which are used to predict acute aquatic toxicity MOA for fish. Verhaar is a QSAR-based system that classifies chemicals into one of 4 classes, with a 5th class specified for those chemicals that are not classified in the other 4. ASTER/Russom includes 8 classifications: narcotics (3 groups), oxidative phosphorylation uncouplers, respiratory inhibitors, electrophiles/proelectrophiles, AChE inhibitors, or CNS seizure agents. Other methodologies include TEST (Toxicity Estimation Software Tool), a computational chemistry-based application that allows prediction to one of 5 broad MOAs (AChE inhibition, narcosis, reactivity, uncoupling, and neurotoxicity), with specific MOAs developed as subcategories. MOAtox is a dataset of MOA assignments for over 1200 chemicals that draws from various schemes and assigns 6 broad and 31 specific acute aquatic toxicity MOAs. Cramer Classification is a widely used approach for classifying and ranking chemicals based on oral systemic toxicity, and is based on short-term or chronic mammalian dietary studies. This scheme is used as the basis for the human health TTC, though its structure-based approach may be useful for ecological applications. Other classification systems that provide insight on a chemicals’ MOA include the Wood Pesticide Compendium, WHO Classification of Pesticides, and other information included in risk assessment tools, such as the USEPA’s EPISuite and the OECD QSAR Toolbox. This presentation will summarize the available MOA assignment schemes, providing a critical evaluation of their limitations and utility.

TU083

Acetylcholinesterase activity, in the orb web spider Agalenatea redii (Scopoli 1763) (Araneae, Araneidae). Characterization and sensitivity to an organophosphate pesticide

C. Mazzia, University of Avignon / Biologie; T. Mazzia, University of Avignon; A. Pasquet, Université de Lorraine CNRS UMR; Y. Capowiez, INRA Institut National de la Recherche Agronomique; M. Rault, University of Avignon

In the European context aiming at reducing the use of pesticides, biological control against pests has to be encouraged and require the protection of beneficial species. Thus studying the effects of pesticide use on current natural enemies is necessary. The spider *Agalenatea redii* is a non-target species, present in apple orchards, and could be a model for both an ecotoxicological and ecological approaches. The objective of this work was to characterize the *A. redii* acetylcholinesterase (AChE) and to assess in laboratory conditions, its sensitivity towards Pyrinex®, an organophosphate insecticide currently used in orchards. We found that AChE is a membrane-bound activity, preferentially located in the cephalothorax, which exhibited a six times higher specific activity than the abdomen (19±5 and 3±0.48 mu.mg^{-1} of protein respectively). This cholinesterase seems to belong to the true acetylcholinesterases as it preferentially hydrolyzed acetylthiocholine (V_{max} = 19±1 mu.mg^{-1}; K_M = 0.124±0,032 mmol.L^{-1}) than butyrylcholine (V_{max} = 10±4 mu.mg^{-1}; K_M = 4,5±3,2 mmol.L^{-1}) and exhibited a strong inhibition for high acetylcholine concentrations. Moreover, the *A. redii* AChE is very sensitive to eserine inhibition (a selective ChE inhibitor) and is selectively inhibited by BW284c51 (a specific inhibitor of AChE) at concentrations in range of 10^{-5} mol.L^{-1}. No inhibition was observed using iso-OMPA, a selective inhibitor of pseudocholinesterase. After one-week exposure to chlorpyrifos-ethyl (Pyrinex®) at 0.33 times the normal application rate, a significant inhibition of AChE activity was observed in the cephalothorax, with a loss of 30% compared to the control. These results suggest that the AChE is a relevant biomarker to study the effect of Pyrinex® on *A. redii* because of its high sensitivity to organophosphate following pesticide exposure. Key words: Acetylcholinesterase ; Spider; Ecotoxicology ; Insecticides

TU084

Stepwise screening scheme for identification of animal testing alternatives

R. Wess, Envigo CRS (Switzerland) Ltd. / Regulatory Consulting

When seeking for registration of a substance, GLP-guideline studies are normally employed on the substance as test item to obtain the basis for an assessment as required by the applicable guidance. Nonetheless there could be other possibilities to reach a meaningful conclusion. Furthermore a systematic evaluation assures avoidance of test artefacts, which may not only produce unnecessary cost and animal consumption, but also the requirement to repeat a study. Generally the following options should therefore be considered first. 1. Waiving an endpoint - Not assessing on an endpoint information requirement\n A short-term effect study may be unnecessary when long-term exposure results exist. In such case the acute toxicity testing may be omitted. 2. Waiving an experiment - Not testing for an endpoint information requirement\n Apart from the three standard waiving arguments, i.e. testing does not appear scientifically necessary \n because existing (literature) data suffice, testing is technically not possible and exposure based (below adequate Threshold of Toxicological Concern), assessment of one endpoint by data from a different one can be possible: Endpoint-Analogy Read-Across: \n e.g. chronic fish toxicity from a carcinogenicity study using fish (US NTP protocol) 3. Analogy approaches (equimolar basis)\n Experimental evidence can be used from tests with surrogates or analogues: Surrogates: \n Identical chemical species liberated (source chemical) with\nanalogue bioavailability due to degradation kinetics or dissociation “Prodrug” \n target chemical forms source chemical as primary degradant “Converging pathway”\n degradation pathways of source and target chemicals lead to formation of a common degradant known to produce the effect “Actual exposure”\n different but non-toxic and thus irrelevant counterion after dissociation Analogues: \n Identical bioavailability after lipophilicity based correction of\nanalogue chemical species sharing a mode of action One-to-one read-across from only one chemical Trend analysis (QSAR) within a larger group forming a category 4. Mixture effect evaluation and calculations\n In a “prodrug” case, if a substance is cleaved into two new substances whereof one is suitable for read-across, both may contribute to the overall effect. Also known impurities should be assessed using the appropriate model (independent or combined action).

Structural Alerts to Predict Excess Toxicity in the Pimephales promelas Assay

N. Ost, Department of Ecological Chemistry; R. Kühne, R. Ebert, M. Hillebrand, G. Schüürmann, Helmholtz centre for environmental research - UFZ / Department of Ecological Chemistry

Since REACH a large number of chemicals have to been evaluated in terms of risks for environment and human health. Further animal tests should be reduced. In aquatic toxicology, *Pimephales promelas* had been used widely as bioassay to study adverse effects of chemical substances. While the toxicity of narcotic compounds can be predicted reasonably well through simple regression equations employing the octanol/water partition coefficient as hydrophobicity parameter since decades. Even though fish toxicity may be interpolated by a read-across approach within a limited chemical domain [1], there are no corresponding general relationships for compounds with specific or reactive modes of action on a mechanistic base. Taking a dataset of more than 900 organic compounds with experimental values for the 50% lethal concentration within 96 h exposure time (LC_{50}), we have developed structural rules that enable the predictive discrimination between narcotic effect level and excess toxic compounds directly from molecular structure with reasonable results. The discussion includes a comparison with established structural alert schemes for daphnids, other MOA-models for fish toxicity and models predicting general reactivity. So far neither the daphnia structural alert models nor the MOA-models are suitable for use in prediction of excess toxicity in *Pimephales promelas* assay. The new model will be combined with the read-across model [1] in a consensus approach, and will be made publically available in computerised form via the software system ChemProp [2]. TU086

Pitfalls in law-abiding long-term fish toxicity testing instead of short-term to reduce animal consumption

R. Wess, Envigo CRS (Switzerland) Ltd. / Regulatory Consulting

With respect to animal welfare the legal text of REACH Regulation (EC) No 1907/2006 states in Annex VIII, whose requirements must be submitted with the dossier at the respective dead line, (Table, 9.1.3, column 1): “*Short-term toxicity testing on fish: the registrant may consider long-term toxicity testing instead of short-term*.” This is based on the consideration that the short-term test can be omitted if long-term data are generated directly (without a previous short-term study), thus using less fish. On the other hand the long-term fish study is an Annex IX endpoint for which it is generally mandatory to submit a testing proposal before conducting a study. In consequence it is possible that no fish toxicity data would be available in the submitted dossier thus making it incomplete. In result the choice when following the column 1 recommendation would be to select between non-compliance with regard to data completeness (lack of fish data) \n or with regard to the duty to follow the test-proposal procedure. Another conflict in fish long-term testing exists in the registration of Medicinal Products for Human use (MPH). A long-term fish early-life stage test is part of the aquatic base set requirements, which has to be conducted if the maximum daily dose (DOSEai) exceeds the action limit of 2 mg/patient and day, but the DOSEai may still be reconsidered until final submission. Independent from DOSEai, an assessment for Persistence, Bioaccumulation and Toxicity (PBT assessment) potentially including fish toxicity testing is nonetheless triggered for substances whose lipophilicity exceeds a Log Kow of 4.5. In this PBT assessment the employment of an alternative test for acute fish toxicity is prescribed. When the substance is found not PBT/vPvB or if the risk characterisation ratio is < 1, a long-term fish test must not be performed. The poster presents the details of these regulatory dilemmas. It is considered for guidance purposes only and should not be regarded either as a personal or company recommendation or a substitute for taking legal or other professional advice.

Johnson & Son, Inc. / Environmental Safety

In order to support the development of an OECD Test Guideline (OECD Project 3.13), a multi-laboratory ring-trial is being conducted to evaluate in vitro methods used in assessing chemical biotransformation in fish involving both trout liver subcellular fractions (S9) and cryopreserved hepatocytes. Substrate depletion methods are used to determine the rate at which both test systems metabolize a series of test chemicals. The goal of the ring trial is to compare in vitro S9 and hepatocyte performance across participating laboratories and S9 performance to hepatocyte performance. In order to inform the study design for the current ring trial, we examined the results from previous multi-laboratory studies with multiple chemicals which used trout hepatocytes and S9 fractions to estimate whole-body rates of chemical metabolism. An analysis of the existing data was conducted using a linear-mixed effects (LME) model which was fit with a restricted maximum likelihood estimation procedure to determine the sources of variability in the data and to estimate the depletion rate. This information from the LME model analysis was subsequently used to set Monte Carlo simulations (>1000) varying the parameters that contributed to the variance in the model (number of time points, replications, chemicals, and laboratories) in order to identify the optimal experimental design for the current ring trial. For each simulation we computed the coverage probability of a 95% confidence interval and mean confidence width. The final study design was developed based upon a small mean confidence width and greater coverage probability in order to achieve a statistically robust study while including practical considerations such as cost, availability of biological material, time, and other critical resources.

TU088

Crossing frontiers - using zebrafish and nematode models for both ecological and mammalian toxicity screening purposes

G. Whale, Shell Health / Shell Health; M. Wildwater, University of Applied Sciences of Arnhem and Nijmegen; P. Racz, ZF-screens BV; R. Pieters, Utrecht University; C.J. Smulders, Shell International B. V. / Shell Health Risk Science Team; R. Dirks, ZF-screens BV; H. Spaink, Leiden University / Institute of Biology; M. Rooseboom, Shell International Limited / Shell Health Risk Science Team

Under the principles of the 3Rs (reduction, replacement and refinement) there is a need for 'animal' alternative toxicity screening assays to assess potential risks to man and the environment. For human health hazard assessment these screening assays need to be translational to humans, have high throughput capability, and from an animal welfare perspective be harmonized with the principles of the 3Rs. To avoid some of the limitations of cell culture systems (i.e. lack of biotransformation capacity, multicellular or multi organ complexity) we have used *Caenorhabditis elegans* (nematode) and *Danio rerio* (zebrafish) larvae models as alternative assays for developmental and reproductive toxicology (DART) hazard assessment of some candidate chemicals. Both models follow the guidelines on the protection of experimental animals (Council of Europe, Directive 2010/63/EU) and are counted as non-animal tests. In our studies the results of the zebrafish and nematode studies were in alignment with data obtained from conventional mammalian toxicity studies indicating that these have potential as developmental toxicity screens. Although their applicability domain has yet to be established it is apparent that there are a number of conserved genetic pathways across the species. In addition to providing mammalian toxicity screening data we believe that, with careful selection of dosing methods and consideration of exposure mechanisms, these models can also provide relevant information for environmental hazard and risk assessment to both aquatic and terrestrial organisms. By combining both mammalian and ecotoxicity considerations into the test designs these models could provide a unique opportunity for environmental and mammalian toxicologists to interact to develop powerful diagnostic tools for a range of applications. For example, such models could have significant potential in screening product categories (e.g. to assess which products should be selected for higher tiered testing) and in screening of water and groundwater samples. In the latter examples the models could be used to provide a more holistic indication of both health and environmental risks from contaminated waters. The models and potential applications will be discussed in the presentation but we recognise that the true potential of such screens will only be realised if we are not 'shackled' by the boundaries of our classical specialisms and embrace an interdisciplinary approach from the outset.

TU089

Score sheets as a tool to enable consistent and comparable identification of the moribund stage in exposed fish in fish acute toxicity tests

M. Teigeler, Fraunhofer IME / Ecotoxicology; K. Kuhl, Bayer CropScience AG; A. Meister-Werner, IBACON GmbH; D. Sacker, Envigo; H. Rufli, ecotoxsolutions

The OECD Guideline 203, Fish acute toxicity test, is currently under revision by the OECD expert groups. In recent years and particularly with Directive 2010/63/EU taking effect in September 2010 including its requirement "to reduce the duration and intensity of suffering to the animal to the minimum possible and ensure a painless death", there has been on-going discussion how to replace this test method or at least ensure tests are compliant with the growing demands of animal welfare legislation. For this reason, the revision process is especially focused on the stage of moribundity. If this stage can unambiguously identified in an exposed animal it should be removed from the exposure tank and humanly killed to avoid unnecessary suffering. The question, how moribund fish are included in the evaluation of the study endpoints, is part of the expert discussion during guideline revision. One of the concerns to this approach is the high degree of subjectivity in the identification of moribundity, a process which requires experienced staff and clear-cut definition of clinical signs/sub-lethal effects to be assessed. The authors suggest implementing a scoring system, which is a standard requirement during performance of animal tests at least in Germany. In this scoring system, parameters are defined which enable different stages of suffering to be classified. The scale includes the stages of; no suffering, mild suffering, moderate suffering and severe suffering resulting in moribundity and eventually death of the fish. The parameters to be assessed include body coloration, behaviour, swimming position and general appearance. Each parameter is scored based on expression of sub-lethal effects and clinical signs. The sum of scores will induce different actions, which includes; enhanced monitoring, contacting the study director and declaration of moribund stage followed by humane killing. The authors present a harmonised scoring sheet provided by different European fish research laboratories. This presentation is intended to deliver further input into the revision process of OECD guideline 203.

TU090

The use of trout liver S9 fraction and cryopreserved trout hepatocytes in substrate depletion assays for the evaluation of xenobiotic biotransformation by fish.

K.M. Johanning, KJ Scientific LLC / dba of Pura Vida Connections LLC; K.A. Fay, University of Minnesota - Duluth / Biology; M. Bernhard, The Procter & Gamble Company / Env Stewardship and Sustainability; I. Bischof, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology; J.W. Davis, Dow Chemical Company / Toxicology and Environmental Research and Consulting; J. Domoradzki, Dow Corning Corporation / Health and Environmental Sciences; M.R. Nichols, U.S. EPA / ORD NHEERL Mid Continent Ecology Division; H. Peterson, DuPont; C. Schlechtriem, Fraunhofer IME / Bioaccumulation and Animal Metabolism; H. Segner, University of Bern / Centre for Fish and Wildlife Health; L. van der Wal, OECD; J.A. Weeks, S.C. Johnson & Son, Inc. / Environmental Safety

Chemical biotransformation represents the single largest source of uncertainty in chemical bioaccumulation assessments for fish. To improve modeled BCF predictions in fish, a substrate depletion assay using trout liver S9 fraction or hepatocytes is a simple means to estimate chemical biotransformation rates. In this approach, a test chemical is incubated with the biological material under first-order kinetic conditions, and the loss of the chemical in the system is measured over time. From the depletion rate, an in vitro intrinsic clearance is calculated, extrapolated to an in vivo clearance, and incorporated in a bioaccumulation model to predict the BCF. A multi-lab ring-trial is underway with the goals of demonstrating the reliability (reproducibility and transferability) of the trout in vitro biotransformation assays, and to support the development of an OECD Test Guideline. Pooled liver S9 fractions and primary hepatocytes were isolated from rainbow trout and characterized using standard substrates to assess both Phase I and II metabolic activity. The material was then provided to six laboratories to perform substrate depletion assays with six chemicals (pyrene, 4-*n*-nonylphenol, cyclohexyl salicylate, fenthion, deltamethrin, and methoxychlor). Incubations were initiated by spiking the test chemical into the reaction mixture in a single test tube, and terminated by pipetting subsamples into a solvent containing an internal standard at pre-determined sampling times. The temperature and pH of the incubation system were the same as the acclimation conditions of the source fish. Preliminary studies were conducted to determine the starting concentration of test article, and the test design was informed by a modeling-based evaluation of hypothetical test data (see companion poster by Embry et al.). These procedures provide a highly standardized test protocol that is optimized for use in comparative biotransformation studies with fish. *The views, conclusions and recommendations expressed in this poster are those of the authors and do not necessarily represent the policies or positions of the European Commission, the OECD, or the United States Environmental Protection Agency.*

TU091

An intestinal fish cell line of rainbow trout (RTgut-GC) for predicting fish acute toxicity of poorly soluble substances

H. Schug, Eawag - Swiss federal Institute of Aquatic Science and Technology / Environmental Toxicology; M. Hülskamp, Eawag Swiss federal Institute of Aquatic Science and Technology / Department of Environmental Toxicology; F. Begnaud, Firmenich / DRAP; C. Debonneville, F. Berthaud, S. Gimeno, Firmenich; K. Schirmer, Eawag / Environmental Toxicology

Various approaches are investigated with the goal to reduce and replace the use of animals for testing of chemical substances. Fish are being used in environmental risk assessment as well as for the testing of industrial effluents. Thereby the Fish Embryo Toxicity test (OECD 236) has already been validated as suitable alternative. Research onto the use of fish cell lines has shown as well to accurately predict fish acute toxicity. Specifically the *in vitro* cytotoxicityassay based on the rainbow trout (*Oncorhynchus mykiss*) gill cell line is suitable for a variety of organic chemicals. Other than the fish gill, the intestine of fish is considered a major route of exposure and uptake of chemicals, especially for persistent and very hydrophobic substances. When present in water, such substances may adsorb to particles that may be taken up by the oral route. We hypothesize that a novel intestinal cell line of rainbow trout (RTgut-GC) is equally able to predict fish acute toxicity for less water soluble compounds. If proven to be true, this approach may be used to test hydrophobic chemicals, such as fragrances, for regulatory purposes and to reduce the use of animals in a laboratory test. The cytotoxicity of selected hydrophobic fragrances towards the RTgut-GC cells was quantified using previously established protocols. The assays are based on the combination of three fluorescent dyes as a measure of metabolic activity, cell membrane integrity and lysosomal membrane integrity. Fragrances were selected to cover a range of physicochemical properties. Specific extraction and quantification methods were developed and were successfully applied for samples from the cytotoxicity assays to quantify truly present chemical concentration. Dose-response curves were calculated based on nominal and measured concentrations and cytotoxicity values were expressed accordingly. Finally, effect concentrations showing 50 % effect (EC_{50} values) were calculated and compared with concentrations showing 50 % death in fish (LC_{50}) from *in vivo* experiments. We were able to show a very good agreement between *in vitro* and *in vivo* values. In summary, the rainbow trout gill cell line (RTgill-W1) assay was successfully transferred to the intestinal cell line from rainbow trout (RTgut-GC) and applied for the testing of hydrophobic organic chemicals. As was previously shown for RTgill-W1, the RTgut-GC produced acute cytotoxicity data that are predictive of the acute fish data.

TU092

Conduction velocity measurements to assess earthworm exposure to insecticides

K. Munir, Lincoln University; C. Mazzia, University of Avignon / Biologie; M. Wellby, Lincoln University; M. Rault, University of Avignon; Y. Capowiez, INRA Institut National de la Recherche Agronomique; R. Gooneratne, Lincoln University

Earthworms are important soil organisms. In agricultural soils, they are potentially exposed to many pesticides. There is a current need for reliable and simple biomarkers to assess the effects of pesticides on earthworms. Among these pesticides, insecticides, especially the neurotoxic ones, represent the highest threat to earthworms. Thus evaluation of the nervous activity by studying the nerve conduction velocity (NCV) could be a relevant biomarker. The aim of this study was to evaluate the effects of 2 insecticides, a carbamate (Pirimicarb) and an organophosphate (Lorsban), both inhibitors of acetylcholinesterase (AChE) enzyme activity on the NCV of *Aporrectodea caliginosa* belonging to the genus of earthworms in the family Lumbricidae. NCV of the medial giant fibers was recorded on days 1, 2, 3, 4 and 7 following exposure to 3 insecticide doses (0.5X, 1X, 5X where X is the predicted environmental concentration based on the normal field application rate) and a control. AChE activity of *A. caliginosa* homogenates was measured at the end of the experiment. A significant decrease in NCV was observed with Pirimicarb on days 3, 4 and 7 for doses 1X and 5X. AChE activity was significantly decreased for the same 2 concentrations. For Lorsban, no significant changes were observed. This study shows that NCV could be an interesting new biomarker to study the impact of insecticides on earthworms. This physiological biomarker is easy to perform, cheap, quick, does not harm the earthworm and fills a missing link between other biomarkers.

TU093

Effects of the endocrine disrupter triclosan to early life stages of the marine fish "Solea senegalensis"

M.J. Araujo, CESAM & DeBio / Department of Biology and CESAM; M.S. Monteiro, R.J. Rocha, Aveiro University / Department of Biology and CESAM; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM

Early life stages of Senegalese sole (*Solea senegalensis* Kaup, 1858) are theoretically suitable organisms for studying endocrine disruption in marine vertebrates, particularly during the thyroid-mediated metamorphosis. Previous works have described such effects by triclosan in vertebrates, an anti-bacterial used in personal care products. Therefore, our aim was to investigate the adverse effects of this chemical to early life stages of *S. senegalensis*. Exposure to triclosan was performed in two experiments. A first group of eggs in gastrula stage was exposed to 5 concentrations (0.30-1.0 mg /L) until 96 hours post fertilization (hpf). The second group was maintained in culture conditions until 13 days after hatching (dah), corresponding to the period immediately before the onset of metamorphosis, and then were exposed to triclosan during 48 h (0.20-0.90 mg/L). Mortality, malformations, lethargy, fish length and behavioral response (response to light stimulus) were recorded. The LC_{50} of larvae exposed to triclosan from the egg stage until 96 hpf was 0.555 ± 0.020 mg/L, while the LC_{50} of 15 dah larvae exposed for 48 h increased to 0.664 ± 0.001 mg/L. Malformations also increased with triclosan concentration in the first experiment ($EC_{50}=0.393\pm0.016$ mg/L) with notochord curvature and overall delayed development recorded in 100 % of larvae at 0.74 mg/L. Besides, lethargy increased with triclosan exposure ($EC_{50}=0.4123\pm0.0154$ mg/L) and a decrease in fish length was recorded at the lower concentrations tested (0.30 and 0.41 mg/L, $p< 0.05$). No delay in metamorphosis was observed in 15 dah larvae exposed to triclosan during 48 h; however, malformations strongly related with metamorphosis progress (namely, abnormal left eye migration and cephalic region development) were present, affecting up to 77 % of larvae at 0.9 mg/L. On the other hand, no adverse effects were observed in fish length, neither in their behavioral response ($p>0.05$). As thyroid hormones have a key role during embryogenesis and metamorphosis, our results suggest that triclosan might be able to disrupt HPT-axis of *S. senegalensis* causing malformations and the impairment of metamorphosis. Further testing will include the expression of thyroid related genes in order to assess the modes of actions of triclosan during early life stages.

TU094

Reducing repeat testing of regulatory vertebrate ecotoxicology studies through a critical assessment of Test Guideline criteria

N. Burden, NC3Rs; R.S. Benstead, Food and Environment Research Agency / Centre for Chemical Safety and Stewardship; T.M. Blickley, Dow Agrosciences / ACES; M. Clook, CRD, HSE / Environment Branch; I. Doyle, Environment Agency / Evidence Directorate; P.J. Edwards, Syngenta / Central Product Safety Dept; J. Handley, Envigo; T. Hutchinson, School of Biological Sciences, Plymouth University / School of Biological Sciences; E.R. Salinas, BASF SE / Experimental Ecotoxicology; J. Wheeler, Dow Agrosciences

In practice a significant number of regulatory ecotoxicology studies do not comply completely with the corresponding OECD Test Guideline in terms of meeting the stated validity criteria and/or other parameters outlined in the guideline. This can result in much uncertainty for the decision makers evaluating the studies, and ultimately leads to requests for repeat testing when it is unclear whether these data are acceptable. Study directors may also decide to repeat studies due to a perception/uncertainty regarding whether regulatory bodies or sponsors will accept the study. In some circumstances, repetition may be completely justified if overall test performance is affected, for example where environmental parameters are not suitable for the test species. However in other situations, deviation(s) from the study may not affect its scientific robustness and thus the overall test performance, but could still result in a) rejection due to non-compliance with, for example, all the validity criteria set out in the relevant Test Guideline, or b) the study only being used as supportive information due to perceived shortcomings. This project, led by an expert steering group of international academics, regulators and industry scientists, will explore the range of validity criteria and other required/recommended parameters within vertebrate ecotoxicology OECD Test Guidelines and other commonly used standard regulatory guidelines. The project will determine which deviation(s) (or magnitude of the deviation) fundamentally undermines study outcomes and overall test performance (hence necessitating repeat studies), and conversely which do not impact on the scientific quality of studies (thus negating the need for their repetition). For each Test Guideline the key validity criteria and other study parameters will be considered in detail. The project ultimately aims to provide robust evidence to support the expansion, where appropriate, of validity and/or other criteria within vertebrate ecotoxicology OECD Test Guidelines, to increase the utility of studies in regulatory decision making and decrease the need for scientifically robust *in vivo* studies to be repeated. Consideration of the criteria within the Test Guidelines that are undertaken most often and for which the majority of repeat testing occurs will be prioritised. This presentation outlines the objectives and proposed strategy to achieve the project aims.

TU095

Phase two of inter-laboratory validation of the Xenopus Embryonic Thyroid Signalling Assay

A. Sébillot, Watchfrog SA; I. Lopes, University of Aveiro / Biology Department CESAM; M.S. Monteiro, Aveiro University / Department of Biology and CESAM; Y. Onishi, IDEA Consultants; T. Okamura, IDEA consultans; A. Tindall, Watchfrog S.A.; T. Iguchi, National Institutes of Basic Biology; B. Demeneix, Evolution of endocrine regulation, MNHN; G. Lemkine, D. Du Pasquier, Watchfrog S.A.

The Xenopus Embryonic Thyroid signalling Assay (XETA) was designed as a screening assay to provide information on the potential of a test substance to alter the normal functions of the thyroid system. The XETA provides a rapid (< 72h) way to measure the response of embryonic stage tadpoles to potential thyroid disrupting chemicals, allowing a efficient method for screening thyroid disruptors. In addition to serving as a quick screen for thyroid active chemicals, XETA, could serve as a potential alternative method to the *in vivo* Amphibian Metamorphosis Assay (AMA - OECD TG231).The AMA test is based on the study of the metamorphosis of tadpoles after three weeks of exposure to a given chemical, and includes histological examination of the thyroid gland. XETA could provide an alternative test that can be performed quickly, providing information that would be useful for screening large number of molecules or testing environmental samples that couldn't be stored or sampled in large quantities The objective of the validation study is to establish the relevance of the assay by assessing its sensitivity to detect disruption of the thyroid system by compounds active at different points within the thyroid system. The validation is intended to determine the performance and transferability of the assay across a range of both experienced and naïve laboratories. XETA utilizes free-living X. laevis embryonic-stage animals (stage 45 up to stage 47) in a multi-well format to detect modulation of thyroid receptor signaling by potential thyroid active chemicals. The assay is transcriptional-based, and uses a transgenic tadpole line containing the THbZIP genetic construct to detect the activity of Thyroid active molecules that work through various mechanisms. The phase one ring test experiments gave the expected results for the chemicals chosen. A statistical approach was determined and a great consistency of the results was observed between laboratories. The XETA Phase I results demonstrate that the assay provides reasonable sensitivity with the chemicals tested and is reproducible, with a few exceptions, across replicates and labs. The XETA phase II started in fall 2015 and active chemicals with modes of action that were not covered in phase I are tested. Estradiol was selected as an inert chemical to challenge the assay and the statistical analysis procedure. The XETA protocol has been modified in accordance to lesson-learned during the phase one.

Interpreting Biological Effects of Metals and Their Mixtures (P)

TU096

Toxicity of equitoxic and non-equitoxic zinc and cadmium mixtures to Daphnia magna

T.R. Bakx, E.T. Halbesma, F.J. Maidman, University of Amsterdam IBED Institute / Aquatic Environmental Ecology; R.E. Zwaan, University of Amsterdam IBED Institute; M. Schoorl, Bayer; M.H. Kraak, University of Amsterdam IBED Institute / Aquatic Environmetal Ecology

In contaminated ecosystems organisms are generally exposed to mixtures of many chemicals, while toxicity tests are often performed on single substances. In the sparse cases of mixture toxicity testing, almost exclusively equitoxic mixtures are tested in stead of non-equitoxic mixtures. The aim of this study was therefore to compare the toxicity of equitoxic and non-equitoxic mixtures of zinc and cadmium to *Daphnia magna*. To this purpose *Daphnia magna* 48 hour acute immobilisation tests were performed with (non-)equitoxic mixtures of Zn and Cd prepared according to the Toxic Unit concept using separately determined EC_{50} values for Zn and Cd. The EC_{50} values of Zn and Cd were 10177 µg/L and 127 µg/L respectively. The EC_{50} of the equitoxic Zn+Cd mixture was calculated to be 1.09 TU (CL: 0.81-1.38), showing that the equitoxic Zn+Cd mixture was concentration additive. In contrast, the toxicity of the non-equitoxic mixtures of Zn+Cd ranged from more than concentration additive to less than concentration additive, depending on the Zn/Cd ratio. This could be explained by differences in the slope of the concentration response relationships of the individual metals, but this was not the case, since these were 8.4 and 7.6 for Zn and Cd respectively. An alternative explanation is that Zn and Cd possibly compete for binding sites at metallothionein-like proteins. Since non-equitoxic mixtures of Zn+Cd dominated by Cd contained less metals in total (because of the much lower EC_{50} value for Cd compared to Zn), the available metallothionein-like proteins pool could bind a higher part of the Cd dominated mixture than of the Zn dominated non-equitoxic mixtures. Consequently, the daphnids could withstand the Cd dominated non-equitoxic mixtures better than the Zn dominated non-equitoxic mixtures. Given the observed ratio-dependent additivity of Zn and Cd in non-equitoxic mixtures, it is concluded that deviations from equitoxicity may lead to over- or underestimation of the additivity of metals in mixtures.

Effects of metal mixture contamination on a freshwater community: can predictive mixture toxicity models be validated experimentally?

T. Van Regenmortel, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab Unit; C. Nys, University of Ghent / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; K. De Schamphelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

In the EU and world-wide, the assessment and management of potential risks posed by chemicals is almost exclusively based on exposure and effect evaluations of individual substances. Previously, four different methods - combining the concentration addition (CA) model or the Independent Action (IA) model with Species Sensitivity Distributions (SSD) in four different ways - were used, compared and critically evaluated for their ability to predict metal mixture toxicity. However, the validity of these predictions needed to be further evaluated using dedicated laboratory and/or field studies. Therefore, the present study assessed the predictive capacity of these models by evaluating potential risks to a freshwater community exposed to metals occurring in ternary-metal (Cu, Zn, Ni) mixtures. For this experiment, natural surface water and a naturally occurring planktonic community were collected from a pond in The Netherlands. These communities were exposed to metal mixtures in which each metal was present (1) at its biotic ligand model (BLM) based, bioavailability-corrected HC_5 and HC_{50} concentration (i.e. the concentration that is hazardous to 5% and 50% of the species in a community, respectively) as well as (2) at ascending concentrations of metals with a fixed environmentally realistic metal concentration ratio of 12.6 for Zn:Cu and 2.6 for Zn:Ni (on a μg/L basis). Different community structure and function aspects including abundances of different planktonic groups and primary production rates were examined and compared to the fraction of Potentially Affected Species (PAF) per water body. The latter was calculated using CA and IA as predictive mixture toxicity models. In this way, we were able to test the accuracy of predictions of metal toxicity to freshwater communities made by these mixture toxicity models and thus contribute to the risk assessment of metal mixtures.

TU098

Evaluation of Toxicity Effects of Heavy Metal Contaminated Soils on Earthworm (Eisenia foetida) in a Mining Area of Guizhou Province

L. Zheng, G. Wang, Nanjing Insitute of Environmental Sciences

Typical soils contaminated by multiple heavy metals were collected from a mining area in Guizhou province for 28d chronic toxicity assay. Activity of antioxidant enzymes, i.e. catalase (CAT) and superoxide dismutase (SOD), 8-hydroxy deoxyguanosine (8-OHDG) and metallothionein (MT) in the earthworm (*Eisenia foetida*) were determined to evaluate correlations between these indicators and soil heavy metal contents. Feasibility of using these indicators to assess ecological risk of heavy metal contaminated mining soils was investigated. Results showed that the activity of CAT and SOD in earthworms increased firstly, and were inhibited thereafter during the exposure duration. This might suggest that activity of CAT and SOD in earthworm was raised to remove free radicals caused by stress of heavy metal contamination so as to adapt to changes of the environment. The accumulation of metabolites in earthworms after alleviating of metal toxicity inhibited activity of antioxidant enzymes, which led to decrease in CAT and SOD activity. When exposed to sub-lethal heavy metal concentrations, content of 8-OHDG in earthworms showed significant decrease with exposure time. With increase in exposure concentrations, more serious damages on 8-OHDG were observed. Within the exposure duration of 28 days, MT in earthworm played a detoxification role under the stress of heavy metal contamination. MT contents increased after 7 days of exposure and decrease thereafter. This study performs a comprehensive evaluation on ecological risk of typical heavy metal contaminated soils of a mining area based on toxicity assay. Results of this study will be helpful to guide remediation of heavy metal contaminated soils as well as its reuse after treatment.

TU099

Combined effects of interspecies interaction, temperature and zinc on Daphnia longispina population dynamics

D. Van de Perre, Ghent University Laboratory of Environmental Toxicology and Aquatic Ecology / GhEnToxLab; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; K. De Schamphelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

During the last decades, the earth's climate has changed rapidly by human activity. Several studies have already investigated the effect of global warming on aquatic communities. However, most studies have, so far, focused on the effects of single stressors and ignored species interactions, while in nature, multiple stressors and species interactions are present simultaneously. Predicting and understanding the consequences of global warming and species interactions on the effects of chemicals on aquatic populations and communities are a primary goal of ecotoxicological research. The main objective of this study was to assess the combined effect of temperature, interspecific interactions and zinc (Zn) on a *Daphnia longispina* population. During an indoor microcosm experiment, *D. longispina* populations (5 adults and 5 juveniles) were exposed to 2 different temperatures (natural conditions: 16-19°C, global warming prospective: 21-24°C), 2 levels of interspecific interactions (initial abundances of *Brachionus calyciflorus* of 0 & 2900/L) and 3 different Zn concentrations (background, HC_5: 44 μg/l and HC_{50}: 142 μg/l) and were varied in a full 2x2x3 factorial design. During the experiment general water quality (DOC, DIC, pH, and O_2), and *B. calyciflorus* and *D. longispina* abundances were recorded every 3 days, for a period of 4 weeks. Interactive effects between the different stressors on the endpoints were determined by comparing observed abundance values with values predicted with the independent action model. The significance of the interactions (three-way and two-way) and the main effects were tested by using ANOVA's (three and two-way) on log-transformed observed data. By evaluating the combined and interactive effects of temperature, interspecific interactions and Zn on a *D.longispina population*, it can be concluded that there are significant interactions between both stressors. Temperature had a positive effect on the *D. longispina* population growth in the control and HC_5 treatment, but an opposite effect in the HC_{50} treatment. Initial analyses also suggests that the sensitivity of *D. longispina* populations to Zn was affected by the presence of interspecific competition. Overall, our study provides information that aids the discussion about integrating multiple stressor interactions and ecological interactions in risk assessment of chemicals.

The effects of zinc on the structure and functioning of a freshwater community: a microcosm experiment

D. Van de Perre, Ghent University Laboratory of Environmental Toxicology and Aquatic Ecology / GhEnToxLab; I. Roessink, Alterra / ERA team; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; E.E. Smolders, Katholieke Universiteit Leuven / Division Soil and Water Management; T. Van Regenmortel, University of Ghent /

Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab Unit; J. Van Wichelen, Ghent University / Laboratory of Protistology and Aquatic Ecology; P. van den Brink, Alterra/Wageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra; K. De Schamphelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

One of the major problems with risk assessment of chemicals is the extrapolation of laboratory single-species toxicity tests, which oversimplify the actual field situation by ignoring species interactions, to natural populations and communities. Here we test if the $HC_{5\ plankton}$ (bioavailability-normalized HC_5 estimated from chronic planktonic single species toxicity data) for zinc (Zn) is protective for a plankton community and we investigated the direct and indirect effects of both the HC_5 and HC_{50} of Zn on a freshwater community's (zooplankton, phytoplankton and protozoa) structure and function. Microcosms were exposed to 3 different Zn concentrations (background, $HC_{5\ plankton}$: 75 μg Zn/L and $HC_{50\ plankton}$: 300 μg Zn/L) for 5 weeks under controlled environmental conditions. The planktonic groups revealed a consistent $NOEC_{community}$ of 75 μg Zn/L, similar to or higher than the $HC_{5\ plankton}$, thus suggesting the protectiveness of the $HC_{5\ plankton}$ for the plankton-dominated community exposed in this study. At 300 μg Zn/L a significant reduction in cladocerans (direct effect) generally resulted in an increase of rotifers, ciliates and phytoplankton abundances (indirect effect). Additionally, the phytoplankton community shifted in dominance from grazing-resistant to edible species. Contrary to the Species Sensitivity Distribution (SSD) prediction, which identified phytoplankton as the most sensitive species group, only the total chlorophyll and the abundance of 2 phytoplankton species were adversely affected at 300 µg Zn/L, whereas many zooplankton species' abundances were affected. Although the HC_5 estimated from the bioavailability-normalized SSD was overall protective for the plankton community, the SSD was not able to correctly predict the species sensitivity ranking within their community context at the HC_{50}.

Chrome in gulls: A global overview

W.E. Espejo, Universidad de concepcion / Facultad de Ciencias Ambientales Eula; J. Celis, Universidad de concepcion / Facultad de Ciencias Veterinarias; D. González-Acuña, Universidad de concepcion / Departamento de Ciencias Pecuarias Facultad de Ciencias Veterinarias; R.O. Barra, Universidad de concepcion / Aquatic systems; K. Sáez, Universidad de concepcion / Departamento de Estadística Facultad de Físicas y Matemáticas

Gulls are birds that are present in most aquatic and terrestrial ecosystems. These birds are excellent bio-indicators of anthropogenic pollution, because they are opportunistic, omnivores and coexist with humans. They are particularly important to assess the ecosystem´s health and can reflect the environmental levels of pollutants. Chrome is an essential trace element which can become toxic depending on dosage. Cr can affect the immune system and cause damage to kidneys and liver. We reviewed the Cr levels (dry weight) in different species of gulls, depending on the biological matrix analyzed and the geographical location. The highest Cr concentrations were reported in *Larus cachinnans* (9.8 μg/g, n=13), whereas the lowest levels were in *Larus hartlaubii* (0.0013 μg/g, n=10). The highest Cr concentrations were reported in excreta (9.8 μg/g, n=13), and the lowest in the gallbladder (0.24 μg/g, n=5). With regard to the geographic location, the higher and lower Cr concentrations were reported in the Southern Hemisphere (1.54 ± 1.53 μg/g, n=61) and in the Northern Hemisphere (1.15 ± 1.56 μg/g, n = 1842), respectively. According to metal distribution in gull matrices, the Cd levels are as follows: excreta > stomach contents > bones > lung > blood > skin > salt gland > gonads > pancreas > intestine > subcutaneous fat > muscle > kidney > liver > uropygial gland > bones > stomach > eggs > brain > heart > gallbladder. High Cr levels in excreta may correspond to detoxification processes. Since most of the data at global scale are from Northern Hemisphere, future studies should be conducted in gulls from Southern Hemisphere. The droppings of gulls can be a good biological matrix for monitoring Cr. Standardized methodology for Cr detection in excreta is quite needed in order to compare data at global scale. Keywords: Chrome, gulls, pollution, birds. Acknowledgements: Winfred E. Espejo is scholarship CONICYT-Chile for PhD studies. This study was financially supported by FONDECYT-Chile 1140466 granted to R. Barra.

TU102

The physiological modes of action of different metals in Tubifex tubifex.

O. Campana; R. Ashauer, University of York / Environment

Chemical stress induced by metals alters the energetic parameters of the organisms (e.g. decreasing assimilation, increasing costs of maintenance, growth, or reproduction, or posing a direct hazard to the embryo) and in turn some measurable quantity such as reproductive output and/or growth. In this study, the freshwater oligochaete *Tubifex tubifex* was exposed to metal spiked sediments at increasing concentrations of cadmium, copper and nickel (separately). During the 28-day exposure, lethal and sublethal effect parameters were recorded over time (number of adults, juveniles, embryos, production of full and empty cocoons) to construct survival, growth and reproduction time-course patterns. Metal bioaccumulation was also quantified over time, including the subcellular metal partitioning for the characterization of the metabolically available and metal detoxified fractions. Physicochemical variables (salinity, conductivity, ammonia, temperature and pH) were measured for quality control and to determine the relationship between different exposure routes (e.g. particulate and dissolved exposure) and the biological variables. The generation of life-history trait time series (survival, growth and reproduction over time) helps to understand the organism level responses to metal toxicity. These responses represent changes in energy allocation patterns under metal stress and so reveal the physiological modes of action of the metals.

TU103

Combined effect of airborne heavy metals on A549 human lung cancer cells

Y. Choi, Gwangju Institute of Science and Technology; K. Park, S. Kim, Gwangju Institute of Science and Technology / School of Environmental Science and Engineering

Many studies have demonstrated that airborne heavy metals affect adverse effects on human health and are an important key factor of cytotoxicity. Moreover, these heavy metals exist as a mixture in atmospheric environment. However, little investigation was conducted on toxicological study of metal mixture from atmospheric fine particulate matter. The objective of this study was to predict combined effects of airborne heavy metals on in-vitro human cells and obtain a suitable mixture toxicity model. The top three toxic heavy metals (e.g., arsenic, nickel and lead) were selected for mixtures exposed to human alveolar epithelium cells (A549) which were appropriate to testing by inhalation toxicity. Cell proliferation (WST-1), glutathione (GSH), and interleukin (IL)-8 inhibition were observed and applied to the prediction models of mixture toxicity, concentration addition (CA) and independent action (IA) model. For total mixture concentrations, we used half-inhibitory concentration (IC50)-fixed ratio and IC10-fixed ratio of individual toxicity. Results showed that mixture of IC50-fixed ratio was different with IA and CA model in mortality and GSH-relative inhibition. Mixture of IC10-fixed ratio was suitable for mixture toxicity models because of more realistic concentration. IA model (α=0.05, p=0.217) indicated a better agreement with the observed results than CA model (p=0.015) in mortality, indicating dissimilar modes of action. For GSH inhibition, the result indicated a high relevance between observation and prediction by IA (p=0.801) and CA (p=0.360). Meanwhile, IL-8 results were maintained stable and no significant change in immune reaction related to inflammation. In conclusion, biological endpoints are useful with in-vitro tool for estimating toxicity of heavy metals mixture. IA model is rapid prediction model in airborne heavy metal mixture that is combined based on low effect ratio for human health effect.

TU104

Modulatory toxicity effects of metal mixtures on chemosensation and mortality of C. elegans

s. moyson; G. Baggerman, Systemic Physiological and Ecotoxicological Research, University of Antwerp; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; S. Husson, Systemic Physiological and Ecotoxicological Research group - University of Antwerp

The number of anthropogenic sources of heavy metals in soil increased the past several decades. This accumulation creates serious health hazards for diverse animals including humans, hereby remaining a persistent (eco)toxicological concern. While toxic effects of single metals have already been documented under laboratory conditions, very little is known about their interactions and putative additive effects, which occur in the environment. The effects of metals in mixture can be additive, antagonistic or synergistic, and by interacting with each other, metals can severely increase the toxicity. One of the major challenges in ecotoxicology is thus to obtain insights in mixture toxicology to set realistic environmental quality criteria. It is well-recognized that metals can alter neuronal excitability, that they are implicated in neurodegenerative diseases and that they can impair chemosensation. We therefore aim to investigate whether and how metal toxicities modulate the survival rate and (chemo)sensory capacities and how this is translated to the behavioural/organismal level . To do so, we will fully exploit the benefits of *Caenorhabditis elegans* as a unique model for both fundamental neuroscience and (eco)toxicology. Fed adult nematodes will be exposed to copper and cadmium (as single metal and in combination) for 2h, 8h, 24h and 48h to different concentrations.

TU105

Bioaccumulation of elements in brown crabs (Canser pagurus) in relation to salmon aquaculture farming

H.B. Ervik, Norwegian University of Science and Technology / Faculty of Social Sciences and Technology Management; B. Jenssen, Norwegian University of Science and Technology / Biology; T. Finne, Geological Survey of Norway / Geochemistry Team

The worldwide demand for seafood has increased over the past decades, and will most likely increase further in the future. A large amount of the increased demand has been met through marine aquaculture. However, it is possible that surplus undigested or excreted toxic elements originating from aquaculture feed may be bioaccumulated by other important marine human consumption marine resources. The brown (edible) crab (*Cancer pagurus*) is an important marine nutritional resource, and high concentrations of some toxic elements, especially cadmium

(Cd) has been reported in this human food item. Due to trace contents of toxic elements, such as Cd, in aquaculture feed, or due to high excretion rates of toxic elements in farmed salmons, levels of toxic elements may be high in brown crabs that feed in the vicinity of salmon aquaculture farms in Norway. Thus, the aim of the present study was to compare levels of elements in brown crabs caught close (ca. 300 m) to a salmon farm and in a reference area far from a salmon farm (> 3000 m). Brown crabs were collected in the autumn during 2012-2015 at Mausund, Norway, and analyzed for element concentrations in the edible meat. Sea floor sediments were used for time integrated chemical characterization of the crabs' feeding ground, and samples from the two locations were analyzed for the same suite of elements as the crabs. The study showed that in general, there were no differences in the concentrations of elements (B, Se, Cd, Sn, Cs, Hg, Pb, Al, Cr, Mn, Fe, Ni, Cu, Zn and As) in crabs from the two locations. Thus, salmon farming did not appear to affect levels of toxic element in brown crabs caught in the vicinity of salmon farms. However, relatively high levels of Cd were found in some of the crabs, irrespectively of location.

TU106

Nickel stress induces enzymatic and ultrastructural changes in the green microalga Ankistrodesmus falcatus. Implications for Ni regulation

E. Martínez Ruiz, Instituto Politécnico Nacional-ENCB / Zoology; F. Martínez-Jerónimo, Escuela Nacional de Ciencias Biológicas-I.P.N. / Laboratory of Experimental Hydrobiology

Nickel is one of the main toxic pollutants discharged to the environment, at increasing concentrations in the last years due largely to industrial and mining activities. For example, in Mexico, water concentrations can be as high as 1.16 mg L^{-1}. Statistics reveal that Ni production worldwide is about 1.589 million tonnes; among the products that contain nickel are stainless steel, coins, and batteries; for some of these products Ni cannot be substituted with other metals. Phytoplankton is an important community because it acts as primary producers, responsible of organic carbon synthesis and oxygen production (through photosynthesis), being the basis of all the trophic webs in aquatic environments. Nickel is an essential micronutrient that plays an important role in cellular physiology in photosynthetic organisms, but it is toxic at concentrations higher than that required. For this reason, it is important to know how Ni affects the green microalga *A. falcatus* at an enzymatic level and in its ultrastructure when exposed to toxic Ni concentrations. In this study *A. falcatus* was exposed to different Ni^{2+} concentrations, under continuous illumination, at 27 °C during 96 h to determine the IC_{50} value. Considering the IC_{50} value as basis, five concentrations were selected to make the subchronic assays: 1, 4, 5, 8, and 17 μg L^{-1}. Cell density was quantified daily and, at the end of the assay, the activity of catalase, glutathione peroxidase, and superoxide dismutase was measured; scanning (SEM) and transmission electron microscopy (TEM) observations were also done. *A. falcatus* was very sensitive to low concentrations of nickel, being the IC_{50} value 17 μg L^{-1}. Additionally, catalase and glutathione activity increased when this alga was exposed to increasing Ni^{2+} sublethal concentrations. Moreover, SEM images demonstrated morphological alterations observing widened cells with abnormalities. TEM analysis revealed that nickel induced ultrastructural changes including an increased number of polyphosphate granules, reduction in the starch grains number, as well as anomalies in chloroplasts. At the lowest Ni concentration, significant damage in *A. falcatus* was observed; this concentration was much lower than the one established by the Mexican regulation as the allowable Ni content in wastewater discharges (4 mg L^{-1}, average monthly). Results here obtained point out the need to review and modify the permissible limit to avoid toxic effects in phytoplankters.

TU107

Chronic metal mixture toxicity to Ceriodaphnia dubia: a meta-analysis and implementation in ecological risk assessment

C. Nys, University of Ghent / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; E.E. Smolders, Katholieke Universiteit Leuven / Division Soil and Water Management; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; R. Blust, Department of Biology; K. De Schamphelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

Although metals in the aquatic environment mostly occur as mixtures, ecological risk assessment procedures are currently still based on a metal-by-metal approach. However, before metal mixture toxicity can be integrated into risk assessment frameworks, better knowledge on mixture toxicity effects during chronic exposure is needed. In several experiments conducted over the past years, we investigated chronic toxicity of Ni, Zn, Pb, Cu and Cd mixtures to *Ceriodaphnia dubia* in 6 different binary, ternary and quaternary combinations comprising in total 210 mixture treatments. In the present study, we combined all our mixture toxicity data in a meta-analysis to evaluate the following three risk assessment related questions: I) are mixture effects important?; II) is the concentration addition (CA) model a conservative model for mixture toxicity?, III) which of the two commonly applied model mixture reference models (CA or independent action (IA)) describes metal mixture toxicity most accurately? Overall, the mixture effect was significantly different from the effect of the most toxic metal. This indicates that mixture effects are important, and that the current risks evaluation approaches based on a metal-by-metal approach might not be protective for communities exposed to metal mixtures. In general, the CA model was the most conservative model. Additionally, very few (less than 1%) significant synergistic interactions relative to the CA model were observed. The latter confirms that the CA reference model can be used as a conservative first tier in a tiered metal mixture risk evaluation scheme. Overall, the IA model described metal mixture toxicity to *C. dubia* more accurately than the CA model. Finally, a possible tiered approach is presented.

TU108

Mechanism of Heavy Metals Toxicity and Adaptation at Different Levels of Biological Organization in White Sea Starfish Asterias Rubens L.

A. Poromov, V. Fedyunin, A. Smurov, Lomonosov Moscow State University / Department of General Ecology

The main purpose of this work is estimation sublethal effects of individuals and mixture heavy metals at different levels of biological organization on the White Sea starfish *Asterias rubens* L. Methods:At cellular level were estimated coelomic cells in exposure experiments *in vitro* and *in vivo*. Coelomocyte primary cell cultures was used to analyzed enzyme activity by photometric methods (NNR-assay) and gene expression by real-time PCR. At organism level were estimated starfish survival and behavior reaction in exposure experiments as well as metal bioconcentration and bioaccumulation in the all body without dissection. At population level were estimated size structure and abundance in points with heavy metals concentration differences. At community level was estimated association symbiotic fauna in different points also. Some of results: Studied area near White Sea Biological Station of Lomonosov MSU characterized by gradient of metal pollution especially iron contamination. Metal bioaccumulation in starfish was not related to the level of contamination of the environment for all investigated metals Metals can be divided into two groups accumulated in the starfish body (Cu, Zn, Cd, Hg), and does not accumulated (Mg, Fe, Ni, Pb). Two starfish color type was investigated that influence on bioaccumulation. Micronuclei induction related to the level of environment concentration of Ni, Cu, Zn, Pb. Heavy metal bioaccumulation and bioconcentration were compared. Bioconcentration has been observed for all investigated metals, except iron. Experiments showed that Cd and Pb can efficiently bioconcentrate and related to the metal concentration in water. Exposure experiments showed starfish high resistance to heavy metals, the most toxic to the starfish appeared copper. The symbiotic association of starfishes *Asterias rubens* and copepods *Scottomyzon gibberum* Scott even in small areas have differences in the populations that may be associated with both the levels of anthropogenic load, and the features of biotopes. The increased number of copepods thus leads to the activation of immune processes with the increase in cell number in the coelomic fluid of the starfish in the most populated areas. At the same time, these processes may greatly be affected by both the natural features of biotopes (salinity, depth, current speed and the type of biotope) and the anthropogenic factor (heavy metals).

TU109

Effect of thermal prehistory and regime on metal toxicity in the zebrafish (Danio rerio)

A. Pilehvar, Antwerp university / Biology; K.I. Cordery, Universiteit Antwerpen / Biology; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology

The zebrafish has become a valuable vertebrate model organism in a wide range of biological research including ecotoxicology. Although there are several studies on metal toxicity in zebrafish, the effect of thermal background on metal toxicity is poorly documented in this and other model species. Changes in environmental temperature can profoundly change species physiological condition in different ways. In this study we explore whether different temperature regimes affect the organism tolerance against metal toxicity. For this purpose, we defined two main thermal scenarios: **1**.**Temparature shock:** in which fish were exposed to 5 different temperatures (17, 22, 25, 32 and 34 °C) and subsequently exposed to metal spiked waters with Cu, Cd or Cu+ Cd for 10 days. **2. Acclimation:** in which fish were acclimatized to 5 different temperatures for 28 days and then challenged by the same metals or mixtures for another 10 days. The condition of the fish was followed during the experiment, including behavioral and physiological metrics and also water quality was monitored. At the end of the exposure period, whole body metal and major cation (Na, K, Ca and Mg) concentrations were determined using ICP-OES or MS. The results showed that copper was much more toxic than cadmium towards the zebrafish in the medium hard water. However, copper and cadmium together showed a large synergistic effect in the mixture exposures. Fish which experienced a cold temperature challenge had a significantly better tolerance against single and mixture metal toxicity compared to the ones that endured an increased temperature challenge. In single exposures the total body burden of Cu and Cd was significantly higher in high temperature treated fish in comparison to the cold treated ones, but total body burdens is not a good predictor of effect. Analysis of the major electrolytes composition of the body shows that survival strongly depends on the capacity to maintain Na balance. Such an effect was not observed for the other major cations under the metal stress scenarios. The results of these experiments show that the thermal prehistory and temperature

regime plays an important role in determining the tolerance of zebrafish towards the effects of metal exposure.

TU110
Acute toxicity of copper and zinc mixtures to the tropical freshwater cladoceran Macrothrix flabelligera.
M. Spadoto, Sao Paulo University / Water Resources and Applied Ecology Center; A.E. Sueitt, Federal University of Sao Carlos / Chemistry; E.M. Vieira, Sao Paulo University / Departamento de Quimica e Fisica Molecular
Mixtures of metals (such as copper, lead, zinc, etc.) and organic compounds are frequently found in industrial and municipal wastewaters, as well as in urban storm waters. All of these contaminant sources reach the aquatic receiving systems directly or indirectly, but, considering toxicological aspects, the water quality guidelines are generally obtained from acute and chronic bioassays testing individual compounds. Thus, such criteria can't predict the interactions and effects of the compounds associated in mixtures, which is the most plausible way to find them in the environment. In an attempt to add some new knowledge to this scientific gap, the acute toxicity of copper (Cu) and zinc (Zn) was determined for the tropical freshwater cladoceran *Macrothrix flabelligera* and the association of both metals were investigated through ToxCalcMix analysis. For this purpose, the neonates were exposed to five concentrations of $CuSO_4$ (0.78 to 3.00 µg L^{-1}) and $ZnSO_4$ (27.9 to 79.4 µg $L^{-}1$) for 48 hours. The tests were replicated five times. Results from these acute tests were subjected to probit analysis using the PriProbit Program V1.6.3 to determine EC_{50} values. The average for the EC_{50}-48h/Cu was 1.4 µg L^{-1} and EC_{50}-48h/Zn was 46.5 µg L^{-1}. Binary combinations of Cu+Zn had a significant effect on survival of *Macrothrix flabelligera* and this interaction was classified as additive, indicating the enhancement of adverse effects of mixtures of metals compared to the single metals. The results proved the importance of considering chemical interactions in water quality management. In addition, considering the need of searching for sensitive organisms to represent the realities of different ecosystems to achieve a greater success in water resources management, *Macrothrix flabelligera* can be suggested as a potential test organism for tropical studies.

TU111
Ultrastructural effects of chronic exposure to Pb and Cd in hepatocytes of wood mice, Apodemus sylvaticus
M. Vendrell, C. Rodríguez Cariño, E. Rossinyol, F. Cardoso, Autonomous University of Barcelona / Microscopy Facility; M. Durfort, University of Barcelona / Cell Biology; R. Scheifler, University opf Franche-Comté / ChronoEnvironment; A. Sánchez-Chardi, Autonomous University of Barcelona / Microscopy Facility
Lead (Pb) and cadmium (Cd) are two non-essential trace metals (TMs) widely distributed in the environment due to natural sources and anthropogenic activities. They can induce toxic effects in target tissues and cells such as hepatocytes. High resolution electron microscopy, namely transmission electron microscopy (TEM) and scanning electron microscopy (SEM), offers powerful techniques to detect the toxic effects produced by chronic exposure to TMs, from atoms and macromolecules to entire cells. In the present study, we have evaluated the ultrastructural damage of chronic exposure to Pb and Cd in hepatocytes of wood mice, *Apodemus sylvaticus*, inhabiting along a gradient of pollution in the surroundings of the former Pb and zinc smelter of Metaleurop Nord (Nord-Pas-de-Calais, France), combining qualitative and quantitative approaches for TEM and SEM. These ultrastructural parameters have been compared with TMs levels in liver of 64 wood mice live-trapped around the former smelter in 2011. The parameters quantified as biomarkers of hepatocyte damage for TEM and SEM are: localization, ultrastructure, and amounts of α-glycogen, ultrastructural damage and electrodensity matrix of mitochondria, subcellular localization of Pb and Cd, and immunolocalization of matrix metalloproteinases (MMP2 and MMP9). Our results show an increase of all parameters related with cell damage and degeneration in relation to the gradient of pollution. Interestingly, α-glycogen accumulates in relation to Pb levels, whereas mitochondrial damage relates to Cd levels; Pb accumulated in α-glycogen and inclusions of Cd were observed in damaged mitochondria; and heavier localization of cytoplasmic MMPs was found in hepatocytes of mice from polluted sites. These findings indicate the necessity for an effort to study physiological effects of metal pollution at real world conditions in selected species that had previously demonstrated their suitability as bioindicators such as the wood mouse. Then, imaging of ultrastructural effects of chronic exposure to metals offers crucial biomarkers to understand toxic effects in natural populations exposed to anthropogenic stressors such as TMs.

TU112
Comparison of Cadmium accumulation and subcellular partitioning between two marine fish species.
G. Le Croizier, LEMAR UMR CNRSUBOIRDIfremer
Kinetics of accumulation and elimination in liver and muscle of two marine fish species, Dicentrarchus labrax, and Solea senegalensis, dietary exposed to 3.5 ppm dw of Cd are investigated. During 60 days, fish were fed with a prepared diet containing Cd, after which a 30 day depuration period was carried out. No significant impact of Cd on growth occurred; however, significant accumulation of Cd occurred in contaminated fish liver and muscle for both species when compared to unexposed controls, with higher levels of accumulation observed in D. labrax. Concerning Cd depuration, 30 days seems to be a too short period to observe elimination in liver and muscle. Quantification of metallothioneins (MT) in liver by spectrophotometry was carried out. Results show that basal levels in D. labrax liver are higher than in S. senegalensis, although exposure dose seems to be too low to induce MT synthesis. Subcellular partitioning of Cd in liver was also investigated, and results show two very different patterns of metal intracellular repartition in these marine species: D. labrax accumulates more Cd in detoxified fractions (about 50%) than S. senegalensis which accumulates Cd in sensitive fractions (about 90%). Our results show a differential accumulation and repartition of Cd between two marine fish species, and underline variability of interspecific sensitivity in metal contamination.

Bioaccumulation of manganese in an endangered carnivorous marsupial: How does manganese exposure from mining operations affect the health of northern quoll (Dasyurus hallucatus) on Groote Island?
A.b. Amir Abdul Nasir, School of Biological Sciences; F.A. von Hippel, University of Alaska Anchorage / Department of Biological Science; R. Wilson, University of Queensland / School of Biological Sciences
Manganese (Mn) is an element vital for normal cellular processes in all living organisms but deleterious in elevated concentrations. Over-accumulation of Mn in the brain region has been reported to potentially cause a condition known as 'manganism', a neurodegenerative disorder characterized by a range of motor deficiencies, psychiatric disturbances and cognitive problems. However, little is known on how prolonged exposure to lower, atmospheric levels of Mn affects human and whether such exposure impacts natural wildlife populations. To address this knowledge gap, we explored the effect of environmental Mn exposure derived from a large Mn mine on the health of a population of northern quolls (*Dasyurus hallucatus*) on Groote Eylandt. Located in the Northern Territory, Australia, this island has a major Mn mining operation since 1967. In our study, we measured how proximity to the mine was associated with the level of Mn in the environment and the level of Mn accumulated in the hair and organs of the northern quoll. In addition, we are examining how the level of exposure of northern quolls to environmental Mn is associated with (i) motor control deficits, and (ii) altered cortisol level; both of which would indicate long-term health problems from Mn over-exposure. As northern quolls are both terrestrial and semi-arboreal, and thus must consistently traverse variable terrain in complex environments to hunt for prey and find mates, locomotion capabilities are direct measures of fitness and thus relate to the viability of the species on the island. Measuring cortisol level also has health implications for wildlife and humans since elevated cortisol levels are associated with many deleterious endpoints, such as reduced immune response and various disease states. The proximity to the mine was associated with the level of Mn accumulated in the hair and some organs in northern quolls. As Mn levels in hair are shown to be predictive of levels in these organs, so hair is a valid tissue to use for low impact studies (e.g. endangered species). Mn level also had a significant reverse correlation with cortisol level in breeding season, suggesting compromised immunity and reproduction for affected quolls. We demonstrate that ongoing research and monitoring will aid in understanding the costs associated with prolonged, low-level Mn exposure to wildlife health.

Assessment of the toxicity of metal mixtures in microalgae Monoraphidium sp.
A. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos; J. Morales Torres, Universidad Autonoma Metropolitana Iztapalapa / CIENCIAS DE LA SALUD
In this study, an evaluation the effects of metals mixtures: Cd + Cr, Cd + Cu, Cd + Hg, Cd + Mn, Cd + Ni, Cd + Pb, Cd + V, Cd + Zn and Cd + Cr + Cu + Hg +Mn + Ni + Pb + V + Zn in the microalgae *Monoraphidium* sp. was carried. Bioassays were performed with duration of 72 hours to determine the EC_{50}. Subsequently tests with duration of 8 days in which the microalgae were exposed to two sublethal concentrations (EC_{15} and EC_1) were performed to evaluate five biomarkers: Population growth, concentration of chlorophyll, carotene production, production of phenols and lipoperoxidation. The toxicity of metals based on EC_{50} values were (from highest to lowest toxicity): Cu > Cr > Hg > Cd > Zn > Ni > Mn > Pb > V . In bioassays with mixtures of metals was observed that the most harmful combinations was Cd + Cu and the mixture of all metals, agree toxic units calculated. The type of interaction observed in these mixtures was potentiation, with a value of magnification of the effect of 2.3 and 2.5 respectively. In bioassays with mixtures Cd + Cu and Cd + Ni, was observed a decrease in chlorophyll levels. In tests with all mixtures it was detected increased levels of carotenoids and phenols. The highest levels of lipid peroxidation were obtained in bioassays with Cd + Cu + and Cd +Zn mixtures. Because EC_{50} values for Cu, Cr, Ni and Zn metal are lower than those established by the NOM 001-SEMARNAT for discharges in aquatic systems, it is important to continue research and monitoring for responses that indicate the possible damage this microalgae populations by the

action of the discharges and different tensions to prevent irreversible deterioration of the populations in the medium and long term.

Amphipods as models to investigate toxicology of environmental contaminants at the land-sea interface (P)

Development of assays to determine anxiety-like behaviours in crustaceans.

S.A. Kohler, University of Portsmouth / Biological Science; M.C. Bossus, Y.Z. Guler, M.O. Parker, University of Portsmouth; A. Ford, University of Portsmouth / Biological Sciences

Concerns over psycotrophic drugs found in the aquatic environment have necessitated the development of behavioural assays to determine the effects and risk posed by these compounds. Biogenic amines such as serotonin, dopamine and epinephrine are known to control complex behaviours in crustaceans including aggression, movement, and phototaxis. However, it is often difficult to differentiate these without carefully designed experiments. For example, negative phototaxis can be interpreted as scototaxis and positive phototaxis can be interpreted as anxiety-like behaviours. Some recent studies have suggested that invertebrates might be highly sensitive to antidepressants, such as the Selective Serotonin Re-uptake Inhibitors (SSRIs), the Serotonin-Norepinephrine Re-uptake Inhibitors (SNRIs) and Serotonin Antagonist and Re-uptake Inhibitors (SARIs). These drugs alter neurotransmitters in the synaptic cleft by inhibiting its re-uptake into the presynaptic cell, which result in increased stimulation but are also known to effect multiple receptor targets. This ongoing study is currently analysing the effects of a variety of antidepressants on complex behaviours in model crustaceans. Specimens of the amphipod, *Echinogammarus marinus* were exposed to the most prescribed SSRIs (citalopram, sertraline and fluoxetine), SARI (trazodone) and SNRI (duloxetine) at environmentally relevant concentrations from 0.001 to 1 µg/L during acute (1 hour and 1 day) and chronic (8 day) exposures. The movement of the amphipods was tracked using the DanioVision system with EthoVision software for behavioural analysis during 12min alternating dark/light cycles. Results show that light had a significant effect on velocity ($P< 0.001$) indicating escape-related behaviour. Antidepressant concentrations had a significant effect ($P< 0.01$) on velocity for Duloxetine (1hr, 1day & 8days); Sertraline (1hr & 1day) and Fluoxetine (1day); no significant effects were observed for citalopram and trazodone ($P>0.05$). Analyses are ongoing to further differentiate scototaxis, phototaxis, anxiety-like and escape response behaviours. Preliminary results indicate fluoxetine does not influence use of space in a 6-well plate system at any of the exposure concentrations. However, we are currently investigating whether this result may be due to experimental design and test chamber space available to the test organism. These results may have implications for future study design of these types of experiments.

TU116

Frequency of intersex phenotypes of Gammarus pulex (Amphipoda) upstream and downstream from effluent of sewage treatment works.

A. Love, Sparsholt College / School of Biological Sciences; A. Ford, University of Portsmouth / Biological Sciences; N. Crooks, University of Brighton / School of Pharmacy and Biomolecular Sciences

There is unequivocal evidence from around the world that sewage treatment effluent has the capacity to cause reproductive endocrine disruption in many fish species. However, the capacity of these effluents to cause reproductive aberrations in invertebrates communities is less clear. This study aimed to determine the sex ratios, intersex frequency and fecundity of *Gammarus pulex* around two sewage treatment works (STW) of similar output discharging into two chalk rivers (the Test and the Anton) in the UK. *G. pulex* were collected at approximately bi-monthly intervals from several points upstream, downstream, and at the point of effluent discharge. *Gammarus* were measured and categorised as male, female, male intersex and female intersex and embryos were counted from ovigarous females. Greater incidences of intersex were observed downstream of the WTP although only significantly ($p < 0.05$) on the river Test. Though the overall incidences of intersex were quite low, they increased by two to three times at and below the effluent discharge point (~1% upstream and 3% downstream respectively) at both sites. The proportion of males and females that were intersex also increased significantly ($p < 0.05$) around the discharge point (~3.1% and 4.1% respectively) compared to upstream (~0.7% and 2.1% respectively). Unlike other similar studies, there was no difference in the male:female ratio seen between the sample sites, however, there was a significant difference in the sex ratios seen between the rivers. The Anton had a much greater difference in the percentage of males versus females (36.7% and 60.2% respectively, compared to 48.8 and 48.9% in the Test). Fecundity varied between sample points but at both rivers it was significantly higher at or near the discharge point (~1egg mg^{-1} female BW) compared to the upstream site (~0.8 mg^{-1}). In other studies, STW effluent has been associated with increases in the fecundity and frequency of female *Gammarus* as well as changes in ovarian development. These changes have been associated with elevated oestrogenic compounds. To date there have been no reports of elevated intersex frequency in amphipods associated with STW, however, amphipod intersex frequency has been shown to increase around sites impacted by industrial pollution. Suggested causal mechanisms include contaminants either feminising the animals directly, or indirectly through immunosuppression and associated increases in feminising parasites.

TU117

The use of Gammarus embryo in ecotoxicology: Effects of cadmium exposure during embryogenesis in Gammarus fossarum.

H. Arambourou, Irstea Lyon / Laboratoire décotoxicologie; A. DECAMPS, Irstea Lyon; D. Neuzeret, F. Moulin, ViewPoint; H. QUEAU, Irstea Lyon

In animals, the embryo stage could be more susceptible to a toxic exposure than later stages. Nowadays, assays involving vertebrate's embryos, such as fish and frog embryos, are extensively used. Nevertheless, for invertebrates such studies remained rare. The toxicity of environmental compounds in early life stages is of importance because embryo toxicity has been shown directly implicated in population decline. The aim of the present study is to develop an ecotoxicological assay in embryo of *Gammarus fossarum*. *Gammarus fossarum* is an amphipod widely distributed in European freshwater systems. As it contributes to the degradation of the organic matter and it serves as food for many macroinvertebrates, fishes and amphibians, it plays a major role in the food web. After fertilization, embryos were gently removed from the females and directly exposed to increasing cadmium (Cd) concentrations (0 µg/l, 2 µg/l and 4 µg/l) until they hatched. Cadmium is a non-essential metal widely detected in freshwater ecosystems. *Gammarus spp*. are particularly sensitive to this metal. Daily, the mortality was recorded. After hatching, we measured in the neonates: i) the mass, ii) the locomotor activity and iii) the total phenoloxidase activity (both prophenoloxidase and phenoloxidase activities). In arthropods, phenoloxidase is an enzyme involved in the sclerotization of the exoskeleton, the melanization and the immunological response. By comparison with the control group, we observed a slight – but not significant – increase of the mortality during the hatching period in the group exposed to 4 µg/l. The mass of the neonates was not significantly altered by Cd exposure, whereas the locomotor activity was significantly reduced in the group exposed to 4 µg/l. Surprisingly, with increasing Cd concentrations, the prophenoloxidase (an inactive precursor of phenoloxidases) activity was increased whereas the phenoloxidase activity was decreased. These results suggested that embryo of *Gammarus fossarum* might be used as a sensitive life stage in ecotoxicological studies.

TU118

UV irradiation and leaching reduce adverse effects of imidacloprid contaminated leaves for the shredder Gammarus fossarum

D. Englert, Institute for Environmental Sciences / Institute for Environmental Sciences; C. Neubauer, University of Koblenz-Landau / Institute for Environmental Sciences; J. Zubrod, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment

In recent years neonicotinoid pesticides have become one of the most widely used class of insecticides worldwide in agriculture, horticulture, forestry, and tree nursery. One reason for their success is their systemic nature leading to a fast uptake and distribution of these insecticides within treated plants. However, due to their environmental persistence within plants (up to several months), neonicotinoids may enter adjacent surface waters together with the treated plant material (e.g. contaminated leaf litter). There, neonicotinoids may pose a threat to non-target macroinvertebrates, which feed on these leaves (e.g. shredders), and to associated ecosystem functions, such as the breakdown of leaf litter. However, prior to the consumption by shredders, neonicotinoid contaminated leaves may be exposed to sunlight (i.e. ultraviolet irradiation; UV) and experience the loss of water soluble substances during leaching, which might alter the leaves' internal neonicotinoid concentrations. To assess alterations in the toxicity of the photolabile and water soluble neonicotinoid imidacloprid within leaves we used the key leaf-shredding macroinvertebrate *Gammarus fossarum* (Amphipoda) as test species, while its feeding rate over seven days was recorded as ecotoxicological response variable. In two independent experiments, *Gammarus* was exposed to leaves from imidacloprid-treated (0.15 g active ingredient per cm trunk diameter at breast height; soil applied) black alder (*Alnus glutinosa*) trees which were either a) leached in water (for 1, 3 and 7 days) or b) irradiated with UV light (for 24 h at UV-A: 41 W/m^2 and UV-B: 0.15 W/m^2; in addition to 1 day leaching in water) prior to use in the experiment. Contaminated leaves without prior UV or leaching treatment as well as leaves from untreated trees served as positive and negative control, respectively. Both experiments revealed a by ~70% reduced feeding rate of *Gammarus* when exposed to contaminated leaves without prior treatment compared to the uncontaminated negative control. In contrast, treatment of leaves with UV-irradiation (24 h) and leaching (7 days) completely reduced the adverse effects on gammarids' feeding. Therefore, although consumption of neonicotinoid-contaminated plant material adversely affects leaf-shredding organisms and, hence, leaf litter breakdown, results of this study suggest a mitigating effect of UV light exposure and dwelling time in water.

TU119

Development of a SRM-based multiplexed quantitation of protein biomarkers in Gammarus fossarum

A. Charnot, UMR; D.D. Gouveia, Irstea Lyon / UR MALY Laboratoire Ecotoxicologie; a. chaumot, Irstea / UR MALY Laboratoire Ecotoxicologie; J. Lemoine, ISA - Université Lyon 1; O. Geffard, Irstea / UR MALY Laboratoire Ecotoxicologie; A. Salvodor, ISA - Université Lyon 1

Biomarkers are recognized as relevant tools for diagnostic and hazard assessment of aquatic systems. However, few are used in invertebrate species studies. It mainly results from the lack of genomic and/or proteomic data, preventing the development of specific and direct method for the quantification of biomarkers. Recently, a novel proteogenomics approach has emerged for a straightforward strategy to discover proteins in non-model organisms. This approach was applied in the amphipod *Gammarus fossarum*, generating a large proteome dataset and offering the opportunity to develop direct and specific analytical mass spectrometry methods. Selected reaction monitoring (SRM) is a liquid chromatography mass spectrometry based technique for the quantitation of a specific protein of interest. SRM has the ability to detect low amounts (to the picograms per milliliter range) of a targeted analyte, with tryptic peptides as multi-indicators of proteins. Absolute quantification can be performed by the addition of an isotopically internal standard. Targeted proteomics can be performed to quantify simultaneously multiple peptides per protein from the same biological sample. Multiplexing analyses by mass spectrometry is in this case straightforward and offers innovative perspectives in ecotoxicology. Using less biological material, resource investments in terms of organism and experimental maintenance are reduced and yield indicators on each biological sample. Herein, we described a highly-multiplexed MRM-based assay for the determination of proteins biomarkers in *Gammarus fossarum* an ecotoxicological model. The assay uses 71 stable isotope-labeled peptide standards for the quantitation of 40 putative biomarkers of candidate proteins related to essential physiological functions including reproductive cycle or defence mechanism. A good linearity was observed for the spiked peptides in extracted individual and, for the proof of concept, the assays precision and accuracy were determined between 0 and 20 % and between 80 and 120% respectively. The assay presented in this study is easy to use, robust and sensitive. High-throughput capabilities will be established to quantify protein biomarkers in *Gammarus fossarum*. Validation of assay was performed with protein changes assessment throughout contrasted physiological process (sex, reproductive status).

TU120

Dietary uptake of systemic fungicide contaminated plant material affects energy processing and growth of a leaf-shredder

K. Newton, University of Koblenz-Landau; J. Zubrod, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; D. Englert, Institute for Environmental Sciences / Institute for Environmental Sciences; P.T. Baudy, University of Koblenz-Landau / Institute of Environmental Sciences; M. Konschak, University Koblenz-Landau / Institute for Environmental Sciences; S. Lüderwald, Universität Koblenz-Landau / Institute for Environmental Sciences; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment

Leaf-shredding macroinvertebrates can be negatively affected by fungicides if they or their food are exposed to these substances via the water phase. Systemic fungicides, on the other hand, may result in an additional effect pathway; these substances penetrate plants and remain active within the vegetation, rendering possible the transport of contaminated plant parts into aquatic systems during leaf fall or storm events. In a previous study, we showed that the shredder *Gammarus fossarum* preferred microbially conditioned leaves treated with systemic fungicides over control leaves. This may be related to a higher production of carbohydrates but lower investments in self-defense of plants and consequently in the development of a microbial community more palatable for *Gammarus*. Therefore, we tested if this putatively higher quality of leaf material treated with systemic fungicides would translate into effects on energy processing and physiology when such leaves are fed over the long-term. We irrigated *Alnus glutinosa* trees (n=3) with fungicide-free water, a mixture of four systemic fungicides at recommended field rates (azoxystrobin 200 g/ha, cyprodinil 400 g/ha, quinoxyfen 100 g/ha, and tebuconazole 200 g/ha; FR), and at rates 10-times above the field levels (FRx10). The fungicides were applied twice, with a six-week interval. Leaves were picked from the trees six weeks after the last application and were microbially conditioned for 12 days before fed to *G. fossarum* in a 24 days lasting bioassay with a food and medium renewal every 8 days. Gammarids' leaf consumption, feces production and final body mass were measured. While no significant differences were found for feces production, gammarids fed fungicide-treated leaves showed a higher leaf consumption (FR by ~30%; FRx10 by ~12%), while this difference was only significant for FR. Also final body mass tended to be higher in the fungicide treatments (FR by ~5%; FRx10 by ~12%) but was significant only for FRx10. Our data suggest that systemic fungicides can affect shredders' energy processing and physiology if applied at field rates. Considering the usually much higher frequency of fungicide applications (up to 20 per season) than used during this study, further experimentation is recommended to test the effects of more realistic application patterns and their potential consequences for ecosystem structure and function.

TU121

Are waterborne and diet-related effects of fungicides transferable among leaf-shredders?

M. Konschak, University Koblenz-Landau / Institute for Environmental Sciences; J. Zubrod, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; P.T. Baudy, University of Koblenz-Landau / Institute of Environmental Sciences; D. Englert, Institute for Environmental Sciences / Institute for Environmental Sciences; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment

Leaf litter breakdown is of prime importance for the energy budgets of detritus-based stream ecosystems, while an instrumental role in this process is attributed to macroinvertebrate leaf-shredders. Fungicides can, however, affect shredders via both waterborne exposure and their diet as demonstrated for the crustacean *Gammarus fossarum*. Effects mediated via the latter pathway were attributed to the adsorption of fungicides to leaf material and subsequent dietary exposure as well as changes in leaf-associated fungal communities, which are crucial for leaves' food quality for shredders. To test if effect patterns and threshold concentrations are transferable to shredder species, the present study investigated the effects of a mixture of five current-use organic fungicides (MOF) and copper (Cu) on larvae of the caddisfly *Chaetopteryx villosa*. We assessed the fungicides' effects on *C. villosa*'s feeding activity (waterborne path) as well as food choice when offered leaf material microbially colonized in the presence or absence of fungicides (diet-related path). *C. villosa* was less sensitive towards waterborne toxicity than *G. fossarum* with EC20-values being higher by a factor of three and six for MOF and Cu, respectively. In contrast, for food-choice, significant preferences where detected for *C. villosa* at exactly the same concentrations as for *G. fossarum*: a significant preference for unexposed over MOF-exposed leaves was observed at 600 and 3000 µg/L, which is probably explained by a repellent effect. In contrast, the larvae preferred leaves exposed to 250 and 500 µg Cu/L over unexposed leaves, which is most likely explained by Cu-induced shifts in the leaf-associated fungal community. Waterborne toxicity thus appears to be of comparably little relevance for the assessed caddisfly since its low sensitivity (compared to *Gammarus*) results in effect threshold concentrations much higher than field levels. In contrast, diet-related effects seem highly transferable among shredder species. Assuming also a similar relationship between effect threshold concentrations for food-choice reactions and physiological fitness effects due to long-term feeding on fungicide-affected leaf material (factor of ~10) as observed for *Gammarus*, effects via this pathway may also be detected at field-relevant concentrations for *C. villosa*. Currently, we experimentally test this assumption, while affirmative results would further support the importance of this pathway for shredders.

TU122

Corophium volutator: a model marine regulatory test species for chronic sediment testing.

M. Fox, Cefas / Environment and Animal Health

The amphipod, *Corophium volutator* is a model test species for marine and estuarine sediment toxicity testing. They are an ecologically important species to the estuarine habitat involved is sediment bioturbation and as a food source to a number of birds and fish including the Redshank, Dunlin and Flounder. *C. volutator* are already being used as a test species in the 10 day sediment reworker ecotoxicity test (OSPAR PARCOM Proctocol 1995 Part A) as part of the offshore chemical notification scheme (OCNS). There is a growing need in regulation of chemicals for test guidance on chronic marine sediment testing. The American Society for Testing of Material (ASTM) have guidance documents for chronic amphipod testing using amphipods found within United States coastal waters however there is a lack of such guidance for a European equivalent species. The European Food Safety Authority (EFSA) have produced a technical guidance document to assess the safety of feed additives for the environment, this includes feed additives for aquatic animals. The guidance for feed additives in aquatic animal feeds focuses on chronic marine sediment testing and suggests using the ASTM methods. However, the ASTM methods are for North American specific test organisms, which are difficult to source in the UK and Europe and are not as environmentally relevant to European waters as native species. The poster will contain methodology and data from a series of Good Laboratory Practice (GLP) 28 day chronic tests which assess the survival and growth (wet weight and length) of *C. volutator*. The tests conducted have been submitted and accepted for use in regulatory dossiers. Further work is being conducted to assess the potential of an extended 75 day test to incorporate a reproduction endpoint.

Population Dynamics of Parhyale hawaiensis (Crustacea: Amphipoda) in laboratory culture: Comparative endpoints as a tool to measure ecotoxicological stress

B. Burstin, G.L. Ferreira, SCHOOL OF TECHNOLOGY UNICAMP / LEAL

Laboratory of Ecotoxicology and Environmental Microbiology School of Technology; L. Alegretti, LEAL Laboratory of Ecotoxicology and Environmental Microbiology; G. Umbuzeiro, SCHOOL OF TECHNOLOGY -UNICAMP / LEAL; M. Flynn, LEAL Laboratory of Ecotoxicology and Environmental Microbiology

An important step to promote ecotoxicology studies is to find an appropriate model organism that can help both acute and chronic toxicities with reproductive, standardized and comparative results on individual and population levels. The objective of this work is to describe the life cycle, fitness impairment and population dynamics of a laboratory culture of *Parhyale hawaiensis* population through the construction of age-specific life tables for obtaining population rates related to reproductive success. Attending on this manner the suggestion of refinement of specific parameters such as, intrinsic growth rate (r), reproductive potential (R0) and generation time (T) obtained from a field population. Demographic parameters were calculated from the construction of an age-specific life table through the observation of a cohort derived from a *P. hawaiensis* lab culture and compared to logistic growth models built for the same species considering data derived from the construction of a time specific life table from a field population. Differences in generation length are apparent between lab and field populations. The intrinsic rate of increase (r) are higher in lab population (cohort) because they live more and attained larger size with a higher fecundity translated in a higher net reproduction rate (R0). The net reproductive rate R0, which is the average number of female offspring per female per generation, does not provide a reasonably good comparison of absolute fitness differences between field and lab populations because the average generation time T is not the same in both situations [4]. Therefore, the measure of fitness most often used, the so-called Darwinian fitness, which is merely the total number of offspring produced by an animal over its lifetime, is not applicable. In the laboratory environment, where conditions were constant and population densities were low despite rapid population growth, the intrinsic rate of increase is probably the most reasonable single measure of absolute population fitness, even though it is calculated only for females and depends on the assumption of a constant age distribution.

TU124

Parhyale hawaiensis population parameters as ecotoxicological endpoints

L. Alegretti, LEAL Laboratory of Ecotoxicology and Environmental Microbiology; B. Burstin, G.L. Ferreira, SCHOOL OF TECHNOLOGY UNICAMP / LEAL Laboratory of Ecotoxicology and Environmental Microbiology School of Technology; G. Umbuzeiro, SCHOOL OF TECHNOLOGY -UNICAMP / LEAL; M. Flynn, LEAL Laboratory of Ecotoxicology and Environmental Microbiology

Population responses to environmental stress have been evaluated for effects on intrinsic growth rate based on evidence obtained by the established association between declining growth and increased stress and environmental carrying capacity, defined as the size of the population where the population growth is zero, crucial to the perception of toxic effect in natural environments. The objectives of this study include the description of the structure and dynamics of a natural population of *P. hawaiensis* through the construction of time-specific life table in order to obtain population vital parameters to be applied at endpoints for chronic toxicity tests known as LTRE (Life Table Responds Experiment). Such demographic statistics can be used in response to exposure to toxic agents, as well as serve as basis for evaluating the welfare of cultures kept in the Laboratory of Ecotoxicology and Environmental Microbiology Dr. Abílio Lopes, Faculty of UNICAMP Technology - FT / UNICAMP. Using the data of 12 monthly time-specific life tables the parameters mean reproductive potencial (R0), generation time (T) and intrinsic growth rate (r) were calculated in order to model the logistic growth curves. The model was built considering the fecundity obtained through field data as well as lab culture. Values of R0, T and r obtained are presented as the mean values for the 12 monthly samples as 1.56 (+/-0.15), 3.75 (+/-0.35) and 0.09 (+/-0.05) respectively. The model indicates that considering field fecundity and an initial population of 10 individuals, the final population would reach carrying capacity (K) in approximately 35 generations and for lab fecundity in approximately 25 generations. The use of the intrinsic growth rate (r), the reproductive potential (R0) and the generation time (T) is recommended as more potentially effective endpoints for ecotoxicological chronic test with the suggestion that they are refined by experiments with laboratory cultures at controlled conditions. Such basic information on the test species chosen must be seen as of paramount importance if population parameters are to be effectively used as an endpoint in ecotoxicology.

Assessing estuarine quality: A cost-effective in situ assay with amphipods

M. Martinez-Haro, IREC-Instituto de Investigación en Recursos Cinegéticos / Department of Life Sciences; A.J. Pais-Costa, MARE; P. Acevedo, Instituto de Investigacion en Recursos Cinegeticos / SaBio IREC; M. Taggart, Environmental Research Institute / Environmental Research Institute; I. Martins, MARE; R. Ribeiro, Universidade de Coimbra / Centro de Ecologia Funcional; J.C. Marques, IMAR-Institute of Marine Research, Department of Life Sciences, University of Coimbra / Department of Life Sciences

In situ assays based on feeding depression can be powerful ecotoxicological tools that can link physiological organism-level responses to population and/or community-level effects. Amphipods are traditional target species for toxicity tests due to their high sensitivity to contaminants, availability in the field and ease of handling. However, cost-effective in situ assays based on feeding depression are not yet available for amphipods that inhabit estuarine ecosystems. The aim of this work was to assess a short-term in situ assay based on postexposure feeding rates on easily quantifiable food items with an estuarine amphipod. Experiments were carried out under laboratory conditions using juvenile *Echinogammarus marinus* as the target individual. When 60 *Artemia franciscana* nauplii (as prey) were provided per individual for a period of 30 minutes in dark conditions, feeding rates could be easily quantified. As an endpoint, postexposure feeding inhibition in *E. marinus* was more sensitive to cadmium contamination than mortality. Assay calibration under field conditions demonstrated the relevance of sediment particle size in explaining individual feeding rates in uncontaminated water bodies. An evaluation of the 48-h in situ bioassay based on postexposure feeding rates indicated that it is able to discriminate between unpolluted and polluted estuarine sites. Using the harmonized protocol described here, the in situ postexposure feeding assay with *E. marinus* was found to be a potentially useful, cost-effective tool for assessing estuarine sediment and water quality.

Biomonitoring of contaminants in the marine environment: integration of biological and chemical approaches (P)

TU126

Between-year correlation between contamination in blue mussels and recruitment of cod

D. Hjermann, Norwegian Institute for Water Research (NIVA); A. Ruus, NIVA / NIVA

We analysed two sources of data: (1) monitoring data on concentrations of eight contaminants in blue mussels from four areas sin the 1980s, and (2) annual abundance of juvenile (6 months old) Atlantic cod collected in beach seine, in the same years and in the same four areas. A statistical analysis showed that for three of the eight contaminants (HCH-A, HCB, and PCB-153), the optimal model (according to the AIC criterion) included both area (1-4) and year-specific contaminant concentration in mussels. In all cases the covariation between contaminants and recruitment was negative. However, the effect was quite variable. Among the four areas (as opposed to among years), there was no correlation between contaminant burden and abundance of cod recruits. Thus, there appears to be a link between year-to-year variation in contaminant concentrations and recruitment variations in Atlantic cod, when the general difference in recruitment among areas is been taken into account. A possible explanation for the covariation is that both mussel contaminant concentrations and cod recruitment may be affected by the same factors (e.g., climate).

TU127

Seasonal variability in biomarkers in the mussel Mytilus trossulus from the northern Baltic Sea

A. Soirinsuo, Finnish Environment Institute, SYKE / Marine Research Centre; A. Ahvo, K.K. Lehtonen, Finnish Environment Institute / Marine Research Centre

With the enormous number of different substances having potentially or known hazardous properties for marine life makes it practically impossible to assess their risks by chemical measurements only. Furthermore, chemical measurements do not account for long-term sublethal effects or mixture toxicity. To complement chemical measurements in monitoring and assessment of hazardous substances, the use of biomarkers is widely considered as a valid choice. In using biomarkers it is of crucial importance to understand natural variability not related to anthropogenic contaminants; this includes seasonal variability caused by abiotic and biotic factors. Many hazardous substances are known to cause pressure to the oxidative defence system of organisms, measured as responses in antioxidant molecules or biological damage, leading to the state of oxidative stress. However, natural variability in factors such as temperature, nutrition and reproductive status can also cause oxidative stress, often by increasing the metabolism of organisms and, hence, production of reactive oxygen species. In the current work, seasonal variability in selected biomarkers was studied in the mussel *Mytilus trossulus* from the northern Baltic Sea by monthly samplings. The biomarkers measured were lipid peroxidation, superoxide dismutase activity, protein carbonylation and lysosomal membrane stability. In addition, the condition index (CI) of the mussels was determined. All the studied biomarkers showed significant seasonal variability with the most stressful period occurring in May. In springtime, multiple factors are likely to contribute to the observed elevation in oxidative stress in mussels, including the sudden marked increase in available nutrition after the intensive spring phytoplankton bloom, and preparation for spawning. Also, meltwater runoff in coastal areas can temporarily contribute to environmental factors. Based on this study, biomarker analyses for monitoring and assessment of hazardous substances using mussels should in this sea area be avoided during the spring and early summer period. Furthermore, routine examination of the CI is recommended as this provides a good basis for assessing the general health status of the mussels that is often linked with the background levels of many biomarkers.

TU128

Assessment of the state of 2 populations of pearl oyster Pteria sterna

A. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos; C. Caceres Martinez, Universidad Autónoma de Baja California Sur

In this study, an assessment of the state of *Pteria sterna* populations located at 2 sites was performed: a pristine area (Gaviota Island BCS) and an area with anthropogenic influence (La Marina BCS) using 3 biomarkers: Degree of lipid peroxidation, acetylcholinesterase activity and genetic damage (micronuclei). In December 2011, July 2012 and December 2012. fifteen organisms of each site was taken and the evaluation of biomarkers was performed in their gill tissue (lipid peroxidation and genetic damage) and foot (Ache). The results indicated that the most adverse times to the organisms that are found in La Marina was December 2011 and Dicember 2012, at this time important contributions of xenobiotics to this site were detected due to increased rainfall. And bivalves that inhabit on Gaviota Island were December 2011 and July 2012, dates which coincide with increases in water temperature caused by "El Niño" phenomenon. Biomarkers were a useful tool to detect the influence of xenobiotics in juvenile *Pteria sterna*. The degree of lipid peroxidation and evaluation of micronuclei were the most sensitive biomarkers to detect "stressful situations" that occurred in the Marina during the stormwater contributions.

TU129

Application of a battery of bioassays for assessing the effects of WWTP effluent on the aquatic biota

K. Charmpi, P. Makridis, University of Patras / Biology; M. Kornaros, University of Patras / Chemical Engineering; S. Dailianis, Univeristy of Patras / Biology

Since chemical and biological data is considered important for assessing the quality of municipal wastewater treatment plant (WWTP) effluent and its environmental risk, the present study investigates the effects of WWTP influent and effluent on a battery of marine organisms such as the brine shrimp *Artemia franciscana* (formerly *Artemia salina*), the sea bream *Sparus aurata,* and the green algae *Dunaliella tertiolecta,* while primary culture of hemocytes of the marine bivalve mollusk *Mytilus galloprovincialis* was also used for investigating the cytotoxic and oxidative effects of samples. Chemical analysis, primarily performed in samples, showed that WWTP processes efficiently reduce the levels of each parameter tested in effluent. On the other hand, the exposure of the green algae *Dunaliella tertiolecta* to different concentrations of each sample (6.25-50% v/v), showed a significant dose-dependent decrease of WWTP influent-treated algae growth rate, after 24h, compared to that observed in WWTP effluent-treated algae, a fact that attenuated over time (96h). However, a significant depletion of algal growth rate was observed in cells treated with concentrations of WWTP influent higher than 25% v/v. Similarly, a slight attenuation of WWTP effluent toxic effects was observed in the brine shrimp *Artemia salina*, compared to those occurred in case of WWTP influent (24hLC_{50} values of 90.63% and 86.58 v/v respectively). Moreover, *Sparus aurata* larvae incubated with different amounts of WWTP influent and/or effluent (0.001-10% v/v) for 6 days, showed a time-dependent increase of larvae mortality rates. However, among live larvae, significantly elevated developmental abnormalities/deformities were obtained in WWTP influent-treated larvae, at least in case of larvae treated with 10% v/v of influent. Regarding WWTP effluent-mediated cytotoxic and oxidative potency, a significant increase of cell death as well as increased levels of lipid peroxidation were observed in WWTP influent-treated hemocytes of mussels, compared to those occurring in WWTP effluent-treated cells. In conclusion, the results of the present study showed that even if WWTP processes could efficiently remove organic compounds and pathogenic microbes from municipal influent, WWTP effluent disposal could pose a risk for the aquatic environment. The extent of WWTP risk seems to be species-specific, depending mainly on species' vulnerability and sensitivity.

TU130

Imposex in the dogwhelk (Nucella lapillus): twenty two years monitoring around England and Wales

E.E. Nicolaus, Cefas Lowestoft Laboratory / Environment and Ecosystems; J. Barry, Cefas Lowestoft Laboratory

Six imposex surveys in the dogwhelk (*Nucella lapillus*) have been conducted over the past two decades to assess legislation effectiveness controlling the use of TBT by the maritime shipping industry. This study firstly analysed the results of the 2014 survey and secondly carried out a trend assessment of the same 88 sampled sites between 1997 and 2014 of which 65 showed statistically significant reductions. To highlight the magnitude of change the VDS of the same 56 sites sampled in 1997 and 2010 showed that the VDSI reduced statistically significantly from 2.89 and 0.42 respectively. These data confirm that the legislation enacted, latterly through the IMO during 2003 to 2008, has been effective in progressively reducing the impact of TBT in the marine environment. Nevertheless, the 2014 results show that two of 18 sampled sites (Gurnard Bay and St. Mawes) are still above the EAC derived for TBT (VDSI≤2).

TU131

Caging approach comparison of the mussel Mytilus sp and of the sponge Hymeniacidon perlevis in assessing biological effects of harbour seawaters subjected to metallic and organic contaminants

C. Caplat, UMR Borea / physico chemical; O. Basuyaux, Smel; B. Levesque, Université de Caen Normandie; J. Pain, S. Leglatin, Labéo Manche; M. Mahaut, Cnam-Intechmer

Since these last years, different approaches were settled to assess seawater quality in the aim to improve the good chemical status of coastal waters demanded by EU-WFD. One approach is to provide biological model (bioindicator) as environmental sentinel of harmful chemical introduction. The marine model organism which is often retained as integrative matrix of contaminants is the mussel (*Mytilus edulis*), especially within the French networks set up since 1970's years. This species presents criteria retained for bioindicators such as abundance, sedentary, tolerance to physico-chemical variations, and can integrate chronic contaminations of "water masses" over a large period. Moreover, this organism presents some limits as integrative model linked to its reproductive cycle which imposes specific period of study. Since these last years, the research of new bioindicators such as sponges has been developed. The sponges are sessile species without organs (in opposition to bivalve molluscs) whose morphology is adapted to maximize the efficiency of water flow. After a specific study to the identification and distribution of the sponges populations present along the coasts of Normandy, one species (*Hymeniacidon perlevis*) showed promising results in accumulation of different chemical compounds such as metallic and organic contaminants (PCB and HAP). To demonstrate the interest of using this species as bioindicator, natural and local samples of *H. perlevis* and *M. edulis* were transferred in same time by caging in different sites of one harbor in Normandy. Organisms were then exposed to different anthropic sources of contamination in order to compare their accumulation performances. In parallel, tests were performed on this sponge set up in mesocosms to assess copper bioconcentration factor. The aim was to evaluate the in-situ harbor seawater concentration of this element strongly accumulated in sponge tissues. Results will be presented in this work and discussed in the perspectives of the Water Framework Directive.

TU132

Biological-chemical parameters' coupling for the monitoring of trace metal contaminants in food webs: the case study of a land-to-sea continuum in the North-East Atlantic

T. Chouvelon, IFREMER, RBE-BE-LBCM / RBEBELBCM; C. Mouneyrac, Université Catholique de lOuest / UNAM Université Nantes Angers Le Mans Mer Molécules Santé MMS; H. Tavere, IFREMER / RBEBELBCM; D. Auger, IFREMER; C. Bertrand, Université Catholique de lOuest / UNAM Université Nantes Angers Le Mans Mer Molécules Santé MMS; C. Brach-Papa, IFREMER; S. Bruzac, S. Crochet, J. Knoery, E. Rozuel, IFREMER / RBEBELBCM

Biomonitoring of chemical contaminants is positioned at the biological-chemical interface, requiring skills and knowledge in various domains – analytical chemistry, biogeochemistry, biochemistry, ecology and physiology of organisms – in order to be useful to fulfil its role: describe levels of chemicals, interpret them, and assess their potential effects. Biomonitoring can therefore provide a global picture of contaminants in systems, even if general strategies must be amended to fit site-specific constraints such as local physico-chemical forcing variables, occurrence of monitored species, etc. Here, we propose to combine both chemical (metal concentrations, carbon (C) and nitrogen (N) stable isotopes measured in various species), and biological parameters (metallothionein (MT) concentrations, data on the ecology of organisms) to describe contaminants in food webs, taking the Loire estuary as a case study. Thus, ten species (including 7 fish, 2 crustacean and 1 bivalve species) representative of the food web were analysed for these parameters. C and N isotope results traced the different sources organic matter sustaining the different species, assessed their habitat and trophic level, and consequently were crucial in interpreting metal burdens. MT concentrations and metal distribution between soluble and insoluble fractions also revealed differential metal regulation and/or detoxification capacities among the species. For instance, among fish, the microphytobenthos-grazer (then low trophic level) mullet *Liza ramada* presented the highest metal concentrations probably due to sediment exposition, but exhibited an efficient mechanism of regulation and/or detoxification (high MT levels and metal insolubilisation). This integrative approach adds to quantitative monitoring of environmental contaminants because it provides a view of the effective bioavailability of chemicals, and of their transfer and bioaccumulation in food webs – a major component of ecosystems. This study therefore proposes that the combined use of such tools has considerable interest in monitoring programmes that aim at describing the temporal and spatial contaminant variability in ecosystems. Finally, in the perspective of the European Marine Strategy Framework Directive (MSFD) implementation, it represents a concrete example of biological-chemical parameters' coupling to document both MSDF descriptors D4 (Food-web) and D8 (Pollution), and to more broadly monitor contaminants in food webs.

TU133

Genotoxicity assessment in the spermatozoa of the common prawn Palaemon serratus using the alkaline Comet assay

A. ERRAUD, SEBIO UNIVERSITE LE HAVRE / Seine Maritime; B. Xuereb, SEBIO UNIVERSITY OF LE HAVRE; A. Duflot, SEBIO UNIVERSITY OF LE

HAVRE / UMRI SEBIO; J. Danger, SEBIO UNIVERSITY OF LE HAVRE; A. Geffard, Université de Reims Champagne Ardenne; J. Forget-Leray, SEBIO UNIVERSITY OF LE HAVRE / UMRI SEBIO; M. Bonnard, Ecotoxicological Laboratory
Sperm quality is essential for reproduction success. Thus there is an increasing concern to understand how the xenobiotic exposures affect the structure of spermatozoa. The measure of DNA integrity appears as an interesting and relevant marker to assess the sperm quality. Nowadays, majority of ecotoxicology studies was relatively narrow to molluscs and fishes despite the interest to investigate the different phyla. Crustaceans and particularly the marine and estuarine species are still rarely studied despite their ecological importance. The purpose of this study was to develop and optimize the alkaline comet assay in marine and estuarine *Palaemonidae* prawns to assess sperm quality. In first times, an optimization of procedures including the collection of spermatozoa, the maintenance in appropriate media as well as different steps (*i.e.* lysis, denaturation) of the comet assay was performed in *Palaemon serratus*. Then the sensitivity of cellular model was assessed using a variety of well-known genotoxicants with diverse modes of toxic action (*i.e.* UV, H_2O_2, MMS). Results attested the reliability and the sensitivity of the procedure developed. In the second times, DNA integrity of spermatozoa was measured in differentially impacted *Palaemon sp.* populations along the Bay and the Estuary of Seine (*i.e.* the coastal species *Palaemon serratus,* and the estuarine species *Palaemon longirostris*) during the year 2015. The first results suggest important DNA damages in populations from the Seine estuary and a lower effect in populations away from the estuary. In conclusion, this work showed the pertinence and the potential of the alkaline comet assay on *Palaemonidae* spermatozoa in the monitoring of environmental genotoxicity.

TU134

Immune capability of humpback whale cell lines and application in immunotoxicity

M. Burkard, Griffith University / Southern Ocean Persistent Organoic Pollution Program; K. Schirmer, Eawag / Environmental Toxicology; S.M. Bengtson Nash, Griffith University / Southern Ocean Persistent Organic Pollutants Program
Humpback whales have an elevated sensitivity to accumulate persistent organic pollutants (POPs) and chemical pollution may impact animals' health. Measuring the immunotoxicological impact of POPs on wild populations of humpback whales is challenging, however, toxic effects in humpback whales are still poorly understood. In this study we use commercial multiplexed ELISA microarrays as a screening tool to measure and quantify relevant proteins. Gene ontology and ingenuity pathway analysis are applied to identify protein targets involved in immune responses and disease processes. In the used approach over 160 proteins were detected and revealed a big overlap between humpback whale derived cell lines and dermal humpback whale skin biopsies. The cell lines were capable of immune stimulation. Incubation with RAW264.7 conditioned media resulted in concentration-dependent expression of IL-6, TNFα and I-Tac. Immune screening and GO enrichment analysis exhibited overrepresented annotations associated with immune system processes, response to external stimuli and chemotaxis. A multiple stressor approach is applied to analyse the impact of POPs on the immune capability of humpback whale cells. The used microarray is a powerful tool for screening and identification of potential biomarker protein targets associated with immune responses in humpback whale cell lines and dermal biopsies. Thus, we provide a minimally invasive method for the study of the whales' sensitivity and cellular response to chemicals and other environmental stressors.

TU135

Multiple stress effects on marine planktonic microalgae

L.R. Vieira, CIIMAR - University of Porto / Research Group of Ecotoxicology Stress Ecology and Environmental Health; L. Guilhermino, CIIMAR / Department of Biology; L. Guilhermino, ICBAS & CIIMAR, University of Porto / Dept Populations Study Lab of Ecotoxicology
In the present context of global warming, more knowledge on the combined effects induced by temperature changes and mixtures of relevant environmental contaminants is urgently needed. Therefore, the main objective of this study was to investigate the effects of temperature increase (20ºC to 25ºC) on the toxicity of one metal (cadmium) and one polycyclic aromatic hydrocarbon (benz(a)anthracene), alone and in mixture, to the marine planktonic algae *Tetraselmis chuii*. Microalgae cultures were exposed for 96h to different concentrations (0.04 - 20 mgL^{-1}) of the two substances individually and in binary mixtures, at 20 and 25 °C. The effect criterion was the inhibition of culture growth. The increase of temperature by 5 °C significantly increased the toxicity of both contaminants. Toxicological interactions among the stressors were found. The findings of this study highlight the need of more research on the effects of temperature on the toxicity of chemical mixtures.

TU136

Eco-toxicological assessment of lithium adsorbents and long-term monitoring of marine microorganism at lithium-recovery field site

J. KIM, S. Jeong, J. Kim, Korea Basic Science Institute; K. Chung, J. Ryu, Korea Institute of Geoscience and Mineral Resources; H. Yoon, Korea Basic Science Institute / Seoul center
The adsorbents which made by lithium manganese oxide for recovery of mineral resources from seawater were developed by KIGAM (Korea Institute of Geoscience and Mineral Resources) and the effectiveness of lithium recovery was verified. When the field application of large amount of adsorbents in ambient seawater (Okgye Harbor, Gangneung, Korea), it should be consider the impact on marine environments by lithium and manganese. In this study, long-term and periodic monitoring has being carried out to detect changes of marine general factors(i.e. chlorophyll, standing crops of phytoplankton, and concentrations of trace metals) at lithium recovery pilot plant and eco-toxicological effects on marine environment by seawater exposure of lithium adsorbents. First, abundances and species of phytoplankton have been evaluated through monthly interval sampling from February 2013 to May 2015 since phytoplankton is important indicator of primary productivity of marine. Abundance and species diversity of phytoplankton went up to summer from winter during whole periods. Eco-toxicological assessment of lithium adsorbents was performed with Microtox using bioluminescence bacteria *Vibrio fischeri*. The lithium adsorbents was soaked in sterilized seawater and aeration for 1, 3, 5, 7, 10 and 14-day intervals under controlled temperature. As the results, toxicities of adsorbents were found in more than 10 days exposure and maximum EC_{50} concentrations were 61.4%. At this time, concentration of eluted metals such as As, Cd, Cr, Cu, Zn, As, Sn, and Pb were also higher. The study is in progress about eco-toxicological assessment as maximum allowable concentration with species sensitivity distribution (SSD) of monitoring factors. **Acknowledgement** This research was supported by the national research project titled "The Development of Technology for Extraction of Resources Dissolved in Seawater" of the Korea Institute of Geoscience and Mineral Resources (KIGAM) funded by the Ministry of Oceans and Fisheries (Project No. PKF061).

TU137

Toxicity of herbicides used to control the invasive weed Spartina anglica to four invertebrate species inhabiting an Australian saltmarsh

L. Kleinhenz, RMIT University / School of Applied Sciences; J. Shimeta, RMIT University; E. Verspaandonk, D. Nugegoda, RMIT University / School of Applied Sciences
Spartina anglica is recognised as an invasive weed in Australia and as a threat to local flora and fauna. Control efforts include the use of the herbicide Fusilade Forte with the adjuvant Hasten . Anderson Inlet, Victoria, Australia is subject to routine spraying of herbicides for *Spartina* control and little is known of the effects of these chemicals on local invertebrate species. Four species commonly found in Anderson Inlet, *Lumbriculus variegatus, Aglaophamus australiensis, Tatea rufilabris,* and *Allorchestes compressa,* were tested in the laboratory with Fusilade Forte and Hasten alone and as a mixture, using 96 hr acute toxicity tests to estimate median lethal concentrations (LC_{50}). *A. compressa* was the most sensitive species in all tests, and *T. rufilabris* the most tolerant.The herbicide mixture was more toxic to the three marine species, *A. australiensis, T. rufilabris, and A. compressa* than Fusilade Forte alone, with toxicity increasing by 146%, 129%, and 181% respectively. However the mixture was less toxic than Fusilade Forte alone by at least 25% to the freshwater species, *L. variegatus*,. Sub-lethal tests on *T. rufilabris* also revealed a higher toxicity of the mixture compared with the toxicity of Fusilade Forte. The laboratory results indicate that using Fusilade Forte with Hasten is more toxic to non-target marine invertebrates than using Fusilade Forte alone. However, consideration of dilution scenarios in the field suggests that rapid degradation and dilution from the incoming tide would reduce the concentrations to well below the LC50 values measured here, resulting in low risk of acute toxicity to aquatic invertebrates from these herbicides in field sites. Monitoring of field invertebrate communities for a period of one to six months after spraying of herbicides as Fusilade Forte alone or as a mixture, yielded little evidence of detrimental effects.

TU138

Organohalogen compounds in fish biota of Guanabara bay, Rio de Janeiro, Brazil

Y.d. Guida, UFRJ / Biophysics; V. Borges, UFRRJ; D.A. Rocha, Universidade Federal Fluminense / Quimica; F.B. Finco, Inst.Biofisica/UFRJ; J. Torres, Radioisotopoes Laboratory / Environmental Biophysics; W. Vetter, University of Hoheinheim / Food Chemistry
OCPs have been reported as an environmental concern issue, since last decades. Nevertheless, their global threats are still difficult to access due to most researches are focused on selected groups of contaminants while other groups remained unstudied. Persistent organic pollutants are regulated under the Stockholm convention since 2001 and constitute a diverse group of organic substances, which are toxic, persistent, bioaccumulative and tend to long-range transport. Urbanization and industrialization severely contribute to contaminated hotspots and worldwide distribution of organohalogen pollutants. The most anthropogenically disturbed area along the brazilian shoreline is Guanabara bay, situated in Rio de Janeiro state. This estuary is bordered by 12000 industries and four cities, with a total population of about 11 million people. Despite the anthropogenic pressure, Guanabara Bay supplies food and breeding grounds for several wildlife, which makes it an important fishing point to the local market and

population. Focusing on expand the knowledge about organohalogen compounds, we tried to determine some target compounds classified as POPs and non-target compounds, in three fish species with high level consumption, by gas chromatography (GC) coupled to electron capture negative ionization (ECNI) with a quadrupole mass spectrometer (MS). The profile contamination of POPs was mainly composed by polychlorinated biphenyls (PBCs) followed by legacy organochlorine pesticides (OCPs) and PBDEs both natural and anthropogenic compounds, according to the literature. Moreover, the presence of some organohalogen compounds less commonly analyzed as the heptachlorobipyrrole (Q1) and pentachloroanisole (PCA) were found in all samples. Regarding these non-target compounds, Q1 has been previously reported in Guanabara Bay by Rosenfelder *et al*, 2012, in a study which they also document the presence of a new DDT metabolite in the local biota. Pentachloroanisole is a common metabolite of pentachlorophenol (PCP) in fish, although it is not well documented. This product is only used in Brazil in wood protection since 1998, before that it was used as fungicide, algaecide and insecticide. As depicted by our results, legacy and emerging POPs can be easily found in the high polluted Guanabara Bay. This may represent a health risk hazard to fishermen and their families. We suggest that more research ought to be done in order to clarify this issue in the near future.

TU139
Acute and chronic toxicity of chlorine to selected marine species of the Arabian Gulf waters
S. Saeed, ExxonMobil Research Qatar / Environment and Water Reuse Program; N. Deb, ExxonMobil Research Qatar / Environmental; S. Bacha Ben Said, Qatar University / Environmental Science Center; C.S. Warren, ExxonMobil Research Qatar / Environment and Water Reuse Program
Chlorine is extensively used as a powerful oxidizing agent in the countries surrounding the Arabian Gulf for water treatments and biofouling control. The usage has been increasing significantly as demand for water grows considerably both in industry and domestic use. This is due to the fact that it is a well-tested technology, has had a history of long-term worldwide industrial use and is of acceptable cost. In seawater, chlorine produces a mixture of hypochlorous acid and hypochlorite ion. These rapidly react with the bromide ion to form a mixture of hypobromous acid and hypobromite ion. The acute oxidants formed by chlorination are therefore short lived and are not persistent in seawater, but can be quite toxic. Further complicating the environmental concern of chlorination is the production of numerous, and more persistent, compounds formed by complex reactions between chlorine/bromine and the organic constituents of seawater, collectively described as chlorination by-products (CBPs). Many CBPs are persistent and may be toxic to marine organisms subjected to long-term exposures. In order to evaluate the risks of chlorine exposure to Arabian Gulf marine organisms, the aims of this study were to 1) develop protocols for acute and chronic toxicity tests involving native species at different trophic levels, 2) correlate sensitivity to other marine organisms used as indicator species in risk assessments, 3) draw conclusion from the results and explore ways that this could be used for informing environmental management activities. Species were collected from different locations around the coastal areas of Qatar. They were then cultured in the laboratory using conditions of the Arabian Gulf. Species used in the tests include phytoplankton (*Synechococcus sp*.), zooplankton *(Euterpina acutifrons),* pearl oysters *(Pinctada radiata),* sea urchins *(Diadema setosum)* and killifish embryos (*Aphanius dispar)*. Different concentrations of chlorine were either administered as a continuous flow through or via daily renewal. Sensitivity varied across the trophic levels for each species and was found to be in line with other test organisms that are used in established toxicity procedures. All five species used were found to be useful for certain types of toxicity testing. For example, *Pinctada radiata* and*Diadema setosum* were excellent in testing for successful fertilization and early development, while local *Aphanius dispar* embryos were useful for following sub-lethal effects such as malformation and hatchability. Embryos of oysters and urchins were found to be the most sensitive to chlorine. Effect of chlorine was only observed near or after hatching has occurred. Continuous exposure showed more effective than the semi-renewal method. The purpose of this study was to increase the knowledge of chlorine chemistry and toxicity especially the sensitivity towards the Arabian Gulf species. Results obtained reveal that the sensitivities of all five species used in this study are in line with species used internationally in similar tests. Expanding tests with species used in this study to evaluate their sensitivity towards chlorine by-products will further increase our understanding of their chemistry and environmental risk in the Arabian Gulf and will provide a science-based tools for making management decisions. \n <br clear="ALL" />

TU140
The IPOC project : Interactions between POllution and Climate changes, Development of improved monitoring strategy
M. AUFFRET, IUEM / LEMAR UMR; M. FOURNIER, Université du Québec À Rimouski / ISMERUQAR
Anthropogenic pressure (habitat destruction, chemical contamination, eutrophication) is recognized to induce deleterious effects on aquatic ecosystems, especially coastal waters whose production is of major importance for humans. Ongoing climate changes are expected to generate in a next future unexperienced, stressful environmental conditions which will probably deeply affect biota in targeted habitat as rivers and estuaries. These natural systems are linked as a continuum through water transfers. Coastal, intertidal habitats are naturally highly variable, both spatially and temporally. Such environmental conditions make them highly exposed to synergistic effects of pollution and temperature stress. At the basis of the trophic chain, benthic invertebrates, especially filter-feeders, control ecosystem productivity by locally producing a huge amount of biomass and should now be considered as key-stone populations at risk. The project IPOC (2013-2016) is a joined, international project borne by French and Canadian laboratories and companies. This consortium will open research into an exceptionally broad range of habitats, from Artic to Austral regions, for observations in natural populations of mussels (*Dressena spp* and *Mytilus spp*). IPOC scientific rationale relies on a better understanding of the sensitivity of these sentinel species in the continuum freshwater-to-coastal areas and thus their vulnerability to environmental stress. The approach combining observation and experimentation will allow to: 1. Assess the diagnostic capacity of a selection of molecular, cellular and physiological biomarkers for assessing biological effects of the combined action of major anthropogenic stressors in aquatic environments 3. Provide the scientific community and environmental managers with an improved "tool-kit", based on original, up-to-date scientific knowledge, for long-term monitoring of aquatic environments, according to recommendations from international organizations 2. Foresee the capacity of aquatic populations at risk to cope with environments altered by the global change and further, possible alterations of local ecosystem services Keywords: Aquatic ecotoxicology, anthropogenic pressure, bivalve mollusks, biomonitoring *The research project IPOC has been funded by the ANR and NSERC Agencies (joined project France-Canada) for the 2013-2016 period.*

QUASIMEME development exercises to improve world-wide reliability of data in the marine environment
S. Crum, Alterra Wageningen UR / ERA team; J. Harmsen, Alterra, Wageningen-UR / CALM; W.v. Vark, Wageningen University / Soil Quality
An integrated biological-chemical monitoring and assessment of chemical pollution in the marine environment is not only a matter of using chemical analytical methods, biological effects methods such as biomarkers and a modelling tool for interpretation. It needs reliable data and common approaches. Results from different countries including their laboratories are often involved in the necessary investigations. Results from these laboratories should be comparable and used in one single assessment model. Standardization and proficiency testing is not always a solution to improve the comparability of laboratories. Especially if methods are still in development, standardization is not yet an option. Exchange of information by involved scientists and technicians as promoted in the QUASIMEME development exercises has shown to be an effective tool to improve results. QUASIMEME stands for Quality Assurance of Information for Marine Environmental Monitoring. At the heart of the programme is a holistic learn-by-doing spiral. The laboratory performance studies provide the basis of external quality assurance for institutes that make regular measurements in the marine environment. For routine parameters a performance study can be organized on regular basis. For new parameters a more fit to purpose approach is necessary as used in the QUASIMEME development exercises. These improvement programmes may be initiated through a workshop and with a series of Development Exercises to provide detailed tuition, information and test materials tailored to the specific needs of the problem. The workshops to exchange information and experiences are essential. Successful exercises has been organized for perfluorinated compounds, chlorinated paraffins, marine biotoxins, organotin compounds, chlorophyll and passive sampling using seawater, sediments and aquatic organisms. Because a large number of marine laboratories are already member of QUASIMEME, it will not be too difficult to extend the approach to other and new quality parameters in the marine environment.

Development and application of oxidative stress biomarkers and models in ecotoxicology and environmental monitoring (P)

TU142
Integrated chemical and toxicological profiling of surface water samples from Swedish agricultural areas
J. Lundqvist, Swedish University of Agricultural Sciences / Department of Biomedical Sciences and Veterinary Public Health; C. von Brömssen, A. Rosenmai, T. Le Godec, Swedish University of Agricultural Sciences; J. Kreuger, Swedish University of Agricultural Science / Centre for Chemical Pesticides; A. Oskarsson, SLU Dept Biomed Sci Vet Publ Health / Dept of Biomed Sci and Vet Publ Health
Pesticides applied on agricultural land can contaminate ground- and surface water and adversely affect ecosystems and drinking water quality. As part of a Swedish program on environmental monitoring of pesticides, we have collected 161 surface water samples from six small catchment areas representing four large

agricultural regions and two rivers, during the years of 2013-2014. The water samples have been analyzed for residues of 131 pesticides, using GC-MS and LC-MS/MS. Of the analyzed pesticides, 87 were detected in the water samples. The water samples were also used for toxicological profiling *in vitro*, using cellbased bioassays. Oxidative stress response is a sensitive indicator of toxicity, responding to a wide variety of chemicals. We investigated the oxidative stress response exerted by the water samples, by measuring the Nrf2 activity. Furthermore, we measured the aryl hydrocarbon receptor (AhR) activity, indicating induction of metabolism of xenobiotics and cytotoxicity by MTS test. The water samples from the pesticide monitoring program were extracted, concentrated and then analyzed by *in vitro* toxicity testing. No cytotoxicity was observed. A large number of the water samples exerted significant induction of the Nrf2 activity and the AhR activity. The effect was particularly strong in the AhR assay, where 123 of the water samples activated the receptor >2 fold compared to the control. Oxidative stress (Nrf2 activity >1.5 fold compared to control) was exerted by 28 of the water samples. The results did not indicate a correlation between AhR and Nrf2 activities. A correlation was found between Nrf2 activity and season. By stepwise regression a statistically significant positive correlation was found between Nrf2 activity and concentration of five pesticides: diuron, lindane, metazachlor, rimsulfuron and terbuthylazine. These effects remained when area and season were included in the model. In conclusion, we found that a large number of the water samples contained substances that exert oxidative stress and activates AhR *in vitro*. No correlation between the two parameters was found but a positive correlation between Nrf2 and some of the pesticides monitored in the program. The study demonstrates that these bioassays are valuable tools to monitor water quality and evaluate environmental effects of pesticide residues.

TU143

Nrf2 as an oxidative stress biomarker of drinking water from source to tap - association with AhR activity and chemical pollutants

A. Oskarsson, SLU Dept Biomed Sci Vet Publ Health / Dept of Biomed Sci and Vet Publ Health; T. Le Godec, A. Rosenmai, Swedish University of Agricultural Sciences; B. Hellman, Uppsala University / Department of Pharmaceutical Biosciences; L. Ahrens, Swedish University of Agricultural Sciences (SLU) / Dept of Aquatic Sciences and Assessment; R. Troger, K. Wiberg, Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; J. Lundqvist, Swedish University of Agricultural Sciences / Department of Biomedical Sciences and Veterinary Public Health

Drinking water contains a complex mixture of known and unknown chemicals, where the individual compounds may be present in concentrations too low to cause adverse effects, but added together may result in combination effects. Oxidative stress response is a sensitive indicator of toxicity, responding to a wide variety of chemicals. The objective of this study was to evaluate the influence of different steps of water treatment on oxidative stress response by measuring Nrf2 activity. In addition chemical pollutants, cytotoxicity and AhR activity were analyzed in the water samples. Water was sampled from five sites before the intake (including up- and downstream a waste water treatment plant (WWTP), after a sand filter, after a granulated active carbon filter, at the outlet of the drinking water treatment plant (DWTP), and from a nanofilter pilot plant. The samples were concentrated by solid phase extraction with two different adsorbents, HLB and ENV. Chemical analysis was performed by LC/TOF-MS for 124 target chemicals, mainly medical drugs, pesticides and household chemicals. In almost all water samples, with a final concentration factor of 50, Nrf2 and AhR activities were detected. Raw water samples had in general higher activities than samples from inside or taken after the DWTP. No evident decrease in activity from a specific treatment step in the DWTP was detected, except in the nanofilter pilot plant, where activities of Nrf2 and AhR decreased after a filter of old granulated active carbon. An association between Nrf2 and AhR activities was found in many of the water samples. Preliminary results did not indicate any genotoxic activity in the water samples, as measured by Comet assay. No cytotoxic effects were revealed in the water samples. The total concentration of target chemicals followed another pattern and decreased considerably from downstream the WWTP to the inlet of DWTP. No Nrf2 or AhR activity was detected in a sample spiked with all the target chemicals, indicating that the activities in the water samples were not caused by the target chemicals and that other, yet not identified compounds, are responsible for the observed activities. The study demonstrates that these bioassays are valuable tools to monitor water quality and evaluate effects of water treatment.

Fungicide prochloraz induces oxidative stress and DNA damage in vitro

J. Lundqvist, Swedish University of Agricultural Sciences / Department of Biomedical Sciences and Veterinary Public Health; B. Hellman, Uppsala University / Department of Pharmaceutical Biosciences; A. Oskarsson, SLU Dept Biomed Sci Vet Publ Health / Dept of Biomed Sci and Vet Publ Health

Prochloraz is widely used in horticulture and agriculture, *e.g.* as a post-harvest anti-mold treatment. Prochloraz is a known endocrine disruptor causing developmental toxicity with multiple mechanisms of action. However, data are scarce concerning other toxic effects. Since oxidative stress response, with formation of reactive oxygen species (ROS), is a common mechanism for different toxic endpoints, e.g. genotoxicity, the aim of this study was to investigate if prochloraz can induce oxidative stress and/or DNA damage in human cells. We used a cell culture based in vitro model to study oxidative stress response by prochloraz, as measured by the activity of the nuclear factor erythroid 2-related factor 2 (Nrf2), a key molecule in oxidative defense mechanisms. We found that prochloraz is able to induce oxidative stress in cultured human adrenocortical H295R and hepatoma HepG2 cells at non-toxic concentrations. Further, we used Comet assay to investigate the DNA damaging potential of prochloraz, and found that prochloraz at non-toxic concentrations is able to induce DNA damage in HepG2 cells. These are novel findings, contradicting previous studies in the field of prochloraz and genotoxicity. This study reports a new mechanism by which prochloraz may exert toxicity. Our findings suggest that prochloraz might have genotoxic properties.

BEHAVIORAL, OXIDATIVE STRESS AND GENOTOXICITY EFFECTS IN THE POLYCHAETE NEREIS DIVERSICOLOR TO THE CYTOTOXIC DRUG CISPLATIN

T.G. FONSECA, T.L. Rocha, University of Algarve / CIMA; M.J. Bebianno, University of Algarve / CIMA Centre for Marine and Environmental Research

\n Anticancer drugs inhibit the process of cell replication and transcription through interaction with DNA, inducing potential mutagenic, cytotoxic, genotoxic and carcinogenic effects. Concerns about their fate and long-term effects in aquatic invertebrates are arising, due to the continue discharge in waterbodies by municipal and hospital effluents. The aquatic sediment represents an important reservoir for those compounds that can pose a risk to the benthic biota. Guidelines for sediment quality assessment does not include pharmaceuticals as contaminants of concern, and little attention has been paid to the potent effects of cytotoxic drugs to non-target organisms. Cisplatin (cis-diammine-dichloroplatinum II) is an alkylating agent globally administered, which environmental levels range from ng $Pt.L^{-1}$ to μg $Pt.L^{-1.}$ The present study aimed to assess the potential effects of the anticancer drug cisplatin to the benthic ragworm *Nereis diversicolor*, at environmental relevant concentration and worst-case scenarios addressed in waterbodies. Polychaetes were exposed to cisplatin at 0.1, 10 and 100 ng $Pt.L^{-1}$, in systems containing sediment and water (1:4), over 14 days. The multibiomarker approach involved a behavioural assessment and biochemical analysis, including neurotoxicity (AChE), antioxidant enzymes (SOD, CAT, GPXs, GST), and oxidative damage (LPO). Genotoxicity was performed through comet assay. Results showed neurotoxicity in animals exposed to the 100 ng $Pt.L^{-1}$ concentration, by the significant inhibition of AChE ($p< 0.05$). Likewise, the activity of antioxidant system was significantly impaired by depletion of SOD, CAT and GST levels, and overexpression of GPx, at the highest concentration of the drug, which lead to high levels of lipid peroxidation products. DNA damage was not detected in polychaetes as a consequence of intra and interstrand cross-links in DNA, associated to the cisplatin mode of action. The multibiomarker approach confirmed the sensitivity of the polychaete *N. diversicolor* to a potent pharmaceutical of cytotoxic activity, addressing that low concentrations combined with chronic exposure may represent a hazard for representative benthic species of coastal waters.

TU146

Towards an early molecular response in periphytic diatoms to reveal impacts of various contaminants: quantitative gene expression

A. Feurtet-Mazel; M. Baudrimont, Université Bordeaux1; S. KIM TIAM, INRS - Eau, Terre et Environnement; S. Moisset, R. Maury-Brachet, Université de Bordeaux / CNRS; C. Daffe, CNRS UMR 5805; F. Perrier, university of Bordeaux/ CNRS; P. Gonzalez, CNRS UMR 5805

This poster aims to highlight the potentialities of the gene expression tools in diatoms to reveal the different impacts of various contaminants which may be found in the natural aquatic systems. Through three independent exposure experiments of a periphytic diatom species to pesticides (diuron), to metal (cadmium) and to metallic nanoparticles (AuNP), the use of gene expression has shown its efficiency to point their cellular impacts and the metabolic functions affected. Diatoms are unicellular algae responsible for a large proportion of vegetal primary production in upstream watercourses and have therefore an essential role at the basis of the freshwater trophic web. They are excellent ecological indicators at the species level, sensitive to a number of environmental variables (light, temperature, inorganic nutrients) and respond to many types of pollution (eutrophication, organic and metallic pollution). Thus laboratory experiments have been performed to expose different diatoms species: *Eolimna minima*, *Achnanthidium minutissimum*, *Nitzschia palea*, *Gomphonema parvulum and Planothidium lanceolatum* cultivated in lab to various contaminants during 48 hours to 2 weeks. A quantitative global criterion has been estimated (total density) to follow their growth in the experimental conditions in parallel to molecular biology analyses. The expression level of target genes involved in the mitochondrial metabolism (*cox1*, *nd5*, 12S), response to oxidative stress (*sod* Cu/Zn, *sod* Mn, *cat*), detoxification (phytochelatin synthase) and photosynthetic processes (*psaA, d1*), has been determined by real time quantitative PCR. Genetic responses evidenced the impact of pesticides, trace metal and nanoparticules on the mitochondrial metabolism, oxidative stress response and the chloroplast photosystem II. Moreover, the analysis of gene expression was evidenced to constitute an early biomarker of alert to detect aquatic systems pollution. These studies also revealed different levels of tolerance/sensibility facing contamination for the studied species: *Eolimna minima* and *Nitzschia palea* appeared to be more tolerant. The results showed that the development of molecular tools and more precisely the biomarkers is an asset to assess organisms' contamination and water quality.

Toxic Detection of Mine Water by Recombinant Saccharomyces Cerevisiae with a lysosomal Specific Biomarker

S. Bang, Chonbuk National University / Division of Chemical Engineering; N. Nguyen, Chonbuk National University / Bioprocess Engineering; J. Park, Division of Chemical Engineering; J. Yoon, Chonbuk National University / Division of Chemical Engineering; Y. Kim, Chungbuk National University / Department of Microbiology; J. Min, Chonbuk National University / Division of Chemical Engineering

Lysosome which has various enzymes inside is one of the cell-organelle used as biomonitoring tool in environmental pollution. In this study, the expression of lysosomal proteomic in yeast in response with toxic chemicals, such as sodium meta-arsenite and tetracycline was analyzed for screening specific biomarkers. After that, a recombinant yeast contained this biomarker were constructed for toxic detection in pure toxic chemicals and 7 mine water samples. The results indicated that each chemical had an optimal dose at which the fluorescent protein intensity reached the peak. In the case of water samples, the yeast showed the response with sample 1, 3, 4 and 5; whereas there is no response with sample 2, 6 and 7. In conclude, the recombinant yeast showed a high ability of toxic detection in response with several chemicals such as heavy metals and pharmaceuticals. In the case of mine water samples, the response varied depending on the sample content. **Acknowledgement** This work was carried out with the support of "Cooperative Research Program for agriculture Science & Technology Development (Project title: Development of Target-specific Antimicrobial and Neutralizing Agents for Livestock Biological Hazardous Factors, Project No:PJ01052701)" Rural Development Administration, Republic of Korea. Proteomic Analysis of Daphnia magna Exposed to Lead (II) Acetate Trihydrate and Atrazine for Screening Potential Biomarker

J. Min, Chonbuk National University / Division of Chemical Engineering; V. Le, Chonbuk National University / Bioprocess Engineering; Y. Kim, Chungbuk National University / Department of Microbiology

Heavy metals and pesticides are main factors causing water pollution via industrial and agricultural waste. However, it still exists a limitation of well understanding about how these toxics effect the aquatic organisms, expecially at molecular levels. In this study, acute toxicity tests were performed according to EPA protocol (2002) to assess the impacts of Lead (II) acetate trihydrate and Atrazine on aquatic species using a typical freshwater flea *Daphnia magna*. Besides, proteomic analysis was performed to identify proteins involved in the stress responses of *D. magna* to these toxic chemicals. The lethal concentrations LC20 of each chemical, which were determined by previous acute test, were used for a 24 h exposure to the 21 days daphnids before isolating the total protein. The proteomic profile was examined with a pH range from 3 to 10 using 2-DE method and then analyzed with Progenesis software to explore the differentially expressed proteins (DEPs) compared with control organisms. The results showed that there were some up- and down- regulated proteins in *D. magna* responding to these toxic chemicals. The DEPs are helpful to understand the molecular responses of *D. magna* to Lead (II) acetate trihydrate and Atrazine and can be used as novel biomarker candidates to detect these heavy metal and pesticide. This work was carried out with the support of "Cooperative Research Program for agriculture Science & Technology Development (Project title: Development of Target-specific Antimicrobial and Neutralizing Agents for Livestock Biological Hazardous Factors, Project No:PJ01052701)' Rural Development Administration, Republic of Korea. The authors are grateful for their support.

Development of Triclonsan Detecting Biomarker Using Daphnia magna

S. Bang, J. Min, Chonbuk National University / Division of Chemical Engineering; H. Shin, Chonbuk National University / Graduate School of Semiconductor and Chemical Engineering; J. Park, Division of Chemical Engineering; Y. Kim, Chungbuk National University / Department of Microbiology

Triclosan has been used an antibacterial and antifungal agent found in consumer products including toothpaste, soaps, toys and cosmetics. However, it is toxic to aquatic / land organisms, human and environmental. Therefore, there is a need for the development of novel biomarker to monitor the toxicity of the triclosan. In this study, acute toxicity tests were performed according to EPA protocol to assess the impacts of triclosan on the typical freshwater flea *Daphnia magna*. The lethal concentration for 20%(LC20) of triclosan for *D. magna* was determined to be 300μg/L. Additionally, the proteomic profile of treated *D.magna* LC20 was also analysed using two-dimensional(2D) electrophoresis technique. The comparison in protein expression pattern between control and TCS-treated organisms was then carried out using Progenesis software to explore the differentially expressed proteins(DEPs). After that, MALDI-TOF analysis was also conducted to identify the proteins dots of interest selected from 2D gels. The changed protein spots due to triclosan treatment can be used as novel biomarker candidates to detect triclosan as being mentioned above. From MALDI-TOF results, certain promoters that can express certain DEPs were inserted upstream to the green fluorescent protein of plasmid vector. Then plasmid transfection was carried out on Hela cell to confirm the working ability of these promoters. The changed protein spots due to TCS treatment can be used as novel biomarker candidates to detect triclosan as being mentioned above. This work was carried out with the support of "Cooperative Research Program for Agriculture Science & Technology Development (Project No: PJ01051502)" Rural Development Administration, Republic of Korea. The authors are grateful for their support.

Interactive effects of climate change and contaminants: environmental risks and human health implications (P)

Methylmercury (MeHg) and climate change: neurophysiologic and behavioral responses of Senegalese sole Solea senegalensis

E.A. Sampaio, IPMA, I.P.; A. Maulvault, IPMA, I.P. / Division of Aquaculture and Seafood Upgrading; V. Lopes, Marine Environmental Science Centre / Laboratório Marítimo da Guia; V. Barbosa, IPMA / Divisão de Aquacultura e Valorização; R. Alves, IPMA; J. Paula, Marine Environmental Science Centre / Laboratório Marítimo da Guia; P. Pousão, IPMA; M. Diniz, Nova University of Lisbon / Centre of Fine Chemistry and Biotechnology; A. Marques, IPMA, I.P.; R. Rosa, Marine Environmental Science Centre

Methylmercury (MeHg) is an extremely hazardous pollutant. Consequences of MeHg exposure on biota in a climate change context are still unknown. Acetylcholinesterase (AChE) hydrolyzes acetylcholine, a prominent neurotransmitter in all vertebrates, both in the sympathetic and parasympathetic nervous systems. Lateralization produces faster and more efficient responses to external stimuli. *Solea senegalensis* use the bottom as camouflage, thus disruption in bottom-choosing ability and lateralization may prove ecologically disastrous. The brain is divided in morphologically different neural substructures, each playing different roles in neurotransmission and MeHg accumulates at different rates on each substructure. We assessed the effects of joint exposure to MeHg contamination and climate change variables in *S. senegalensis* behavior processes, as well as acetylcholinesterase activity and different brain regions weight (forebrain, optic tectum, cerebellum and brainstem). During 28 days**,** *S. senegalensis* specimens were maintained under three factor crossed treatments: MeHg contaminated feed, pH (ambient CO_2: 8.0, high CO_2: 7.6), and temperature (ambient: 19ºC, high: 23ºC). Behavior was assessed by calculating absolute and relative lateralization using a detour test, and by habitat preference, measuring time spent between two habitats: simple and complex (all tests, n=10). Neural substructures were separated, weighed individually, and AChE was assessed in each region. Relative weight for each was plotted and a linear regression from the control was calculated. MeHg intake correlated with increased time spent in complex habitat, where fish could not camouflage or hide efficiently. In addition, MeHg reduced lateralization on each fish, leading to complete loss of lateralization at populational level. Acidification also led to increased time spent in complex habitat, only in non-contaminated treatments. All four brain regions registered differences in relative weight under different stressors. Optic tectum relative weight decreased under all stressors, whereas other brain regions were increased. AChE data is being analyzed. Climate change variables were as important as MeHg in altering brain region relative size, but were downplayed at an ecological level. Disruption of important behavior processes along with deregulation of neural substructure functions, may lead to decreases in *S. senegalensis* ecological fitness.

Can bivalves recover from short-term exposure to environmental changes? The combined effect of salinity shifts and Arsenic contamination

M. Teixeira, Aveiro University / Biology department; A. Almeida, Universidade de Aveiro / Biology Department and CESAM; C.V. Silva; F.J. Wrona, University of Victoria / Department of Geography University of Victoria National Water Research Institute; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; E. Figueira, CESAM University of Aveiro; R. Freitas, Universidade de Aveiro, Portugal / Departamento de Biologia CESAM

Arsenic (As) is one of the most toxic elements in the environment, especially when in its inorganic form, being listed as priority hazardous substance in the world. Although many authors have investigated the levels of As in sediments and water, and As bioavailability and bioaccumulation patterns in the marine environment, less have addressed the toxicity of this metalloid namely in marine bivalves. Besides As, salinity is also a stress factor for aquatic environments since it can change across spatial and temporal scales, species richness, abundance and spatial distribution but also individuals health status. It is foreseeable that climate changes, predicted for the next 100 years, will cause salinity shifts in estuarine and coastal areas. Beyond this long-term environment alteration, extreme weather events are becoming more frequent which can also lead to salinity fast changes. Salinity changes are also expected to change the sensitivity of aquatic organisms namely to metals and metalloids, due to alterations on their physiological and biochemical characteristics. Salinity changes may also alter the toxic capacity of contaminants by changing their chemical speciation, solubility and adsorption, with consequences to their bioavailability. Thus, the current study assessed the biochemical alterations induced in the clam species *Ruditapes philippinarum* after exposure to salinity shifts (14, 28 and 42 g L^{-1}) and As contamination (0 and 2 mg L^{-1}). The capacity of this species to recover (96h and 28 days) after exposure to both stressors, acting alone and in combination, was also evaluated. After exposure, regardless the salinity tested, clams contaminated with As showed higher concentrations than non-contaminated specimens. After recovery, As concentration in clams decreased, with contaminated and non-contaminated specimens presenting similar values. The results obtained further demonstrated that exposure to As (2 mg L^{-1}) at different salinities (salinities 14, 28 and 42 g L^{-1}) and salinity 42 g L^{-1} (As 0 mg L^{-1}) lead to an increase of lipid peroxidation and detoxification mechanisms in clams, compared with clams non-contaminated under salinities 14 and 28 g L-1. After recovery, at salinities 14 and 28 g L^{-1}, clams previously exposed to As were capable to decrease their oxidative stress to levels found in non-contaminated clams. Nevertheless, at salinity 42 g L^{-1} both contaminated and non-contaminated clams did not survive.

TU152
Transcriptomic response of the aquatic plant Elodea nuttallii to mercury and ultraviolet radiation
N. Regier, University of Geneva / Institute Forel Earth and Environmental Sciences; V. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel; C. Cosio, Geneva University / Institute Forel   Earth and Environmental Sciences
We aimed to investigate the influence of enhanced UV radiation on the response of the aquatic plant *E. nuttallii* to interacting stresses. In the present work we exposed *E. nuttallii* to UV (0.55 Wm^{-2} UV_{BE}) for 6 h and to Hg for 24 h or to both for combined treatment. We analysed Hg content, oxidative stress response, effect on pigment content, as well as the transcriptome. UV radiation decreased Hg uptake in shoots as compared to plants exposed to Hg alone. Pigments tended to decrease in response to UV and Hg, and a cumulative effect of combined treatment was observed. Looking at oxidative stress enzymes, we observed an opposite effect of combined treatment: peroxidase activity was significantly decreased by UV and Hg treatments alone, whereas a combination of both abolished this effect. Results of RNA-Seq confirmed results obtained from analysis of pigments and stress response. At the transcriptome level, in terms of stress response, combined exposure had more severe effects than Hg or UV single exposures. Briefly, we found genes involved in sugar metabolism and oxidative stress to be up-regulated, and many photosynthesis-related genes to be down-regulated by combined Hg and UV exposure. In conclusion, we were able to show that UV exposure influences accumulation and tolerance to Hg.

TU153
Combined effects of temperature and cadmium on membrane phospholipid composition, aerobic and antioxidant capacities and lipid peroxidation in two freshwater fishes
M. Fadhlaoui, INRS - Eau, Terre et Environnement / Centre Eau Terre Environnement; P. Couture, INRS / Centre Eau Terre Environnement
In ectotherms, temperature acclimation is always accompanied by membrane fatty acid remodelling and modifications of aerobic and antioxidant capacities. However, metal exposure can alter the capacity of organisms to cope with stressful conditions. In this context, this study investigated the combined effects of temperature and cadmium (Cd) exposure on membrane fatty acid composition, aerobic capacity (determined by the activities of cytochrome c oxidase (CCO) and citrate synthase (CS)), antioxidant enzymes activity (superoxide dismutase (SOD), catalase (CAT) and glutathione peroxidase (GPx)) and lipid peroxidation (malondialdehyde (MDA) concentration). Two freshwater species, the fathead minnow (*Pimephales promelas*) and the yellow perch (*Perca flavescens*), were acclimatized at two different temperatures, 15?C-30?C and 9?C-28?C respectively, for eight weeks in the presence or absence of Cd (8ug /L). At low temperatures, the membranes of two species were enriched in polyunsaturated fatty acids (PUFA) while the proportion of saturated fatty acids (SFA) decreased, a well-established homeoviscous response aimed at maintaining membrane fluidity. This normal response was altered in the presence of Cd. In yellow perch muscle, the proportion of PUFA decreased at 9?C and increased at 28?C compared to control fish at the same temperatures. In the muscle of Cd-exposed fathead minnows, PUFA increased at 28?C but was not modified at 15?C. In the latter species, CCO activity was increased by two-fold at 9°C compared to 28°C but unaffected by Cd. In contrast, in yellow perch, CCO activity was not affected by temperature but it was inhibited by Cd. Antioxidant enzymes (SOD, CAT and GPx) reacted differently between the two species to the two stressors but MDA concentration was consistently higher under cold conditions. The activity of CCO was strongly correlated with PUFA percentage, especially in fathead minnows. The dominant PUFA were arachidonic, eicosapentaenoic and docosahexaenoic acids. These fatty acids are among the major constituents of cardiolipin. Consequently, we hypothesize that the observed modifications in CCO activity were mostly due temperature or Cd-induced modifications of fatty acids surrounding this enzyme. Our study demonstrates that physiological responses to thermal acclimation can be affected by metal exposure, highlighting the importance of studying the interaction of multiple stressors.

TU154
Levels and trends of contaminants in human populations in the Arctic
J.C. Gibson, B. Adlard, Health Canada; K. Olafsdottir, University of Iceland; T.M. Sandanger, UiT The Arctic University of Norway
The Arctic Monitoring and Assessment Programme (AMAP) is one of six working groups (WG) established under the Arctic Council. AMAP is tasked with monitoring the levels of contaminants present in the Arctic environment and people as well as assessing their effects on a continuous basis, and reporting these results regularly. This presentation provides an overview of the human biomonitoring data from all eight Arctic countries reported in the 2015 Human Health Assessment Report. Levels of contaminants are declining in the monitored Arctic populations, but not consistently across the Arctic. Certain populations are experiencing more rapid declines than others, and certain populations have concentrations that are remaining stable or are still increasing. Most Arctic populations described in this chapter continue to experience elevated levels of these contaminants compared to other populations monitored worldwide, for example, mercury, where 7 to 85% of Inuit women 18 to 39 years of age in Arctic Canada and Greenland exceed the Canadian provisional blood guidance value of 8 ug/L established for children and women of childbearing age. There are certain contaminants, like perfluorinated compounds (PFCs) and polybrominated diphenyl ethers (PBDEs) which are still increasing in Arctic populations, and require more investigation to find the predominant and important sources of exposure. Most of these data have been collected over the last twenty years and are from all 8 circumpolar countries. Coordinated, international biomonitoring must continue in the future to determine if levels of these contaminants, and others, are changing in Arctic populations. This work continues to support international risk management efforts under the Stockholm Convention. This work also supports the objectives of Canada's Chemicals Management Plan.

TU155
Ecophysiological responses of Gammarus pulex to the combined effects of temperature and ammonia
Y. Henry, UMR   CNRS   ECOBIO; C. Piscart, H. Colinet, Université de Rennes 1 / UMR CNRS   ECOBIO; S. Charles, University Lyon 1 / Laboratory of Biometry and Evolutionnary Biology
In freshwater ecosystems, accumulation of pollutants mostly results from anthropic activities. Today, it is a worrying issue due to potential drastic consequences on aquatic biodiversity . Ammonia appears among compounds that may act as a threatening contaminants for many species. In water, ammonia concentration heavily depends on both temperature and pH. Therefore, we investigated the effects of temperature (10, 15, 20 & 25°C), ammonia concentration (0, 0.5, 1, 2, 3 & 4 mg/L), and their combination, on the survival ability and the molecular responses of *Gammarus pulex*, a common freshwater crustacean. Survival experiments revealed an unexpected trend toward an antagonistic interaction between the two parameters. While a week of exposure to 25°C induced a 43% reduction of survival in the absence of ammonia, the addition of a high ammonia concentration (4mg/L) blurred the stressful effect of the temperature. Indeed, in the 4 mg/L condition, the survival was 10% higher at 25°C than in the 10°C condition. The analysis of survival data through Bayesian toxico-kinetics/toxico-dynamics (TK-TD) models confirmed this antagonistic interaction. Between the 10°C and the 25°C exposure treatments, ammonia Lethal Concentration for 50% of individuals (LC_{50}) estimates increased from 2.56 to 5.4 mg/L and ammonia No Effect Concentration (NEC) estimates increased from 0.90 to 1.25 mg/L respectively. Using qPCR techniques, we also tried to associate these survival patterns to variations in the expression of the *hsp70* gene, a generic biomarker of stress. Gammarids exposed to 25°C showed a 14-fold change overexpression of *hsp70* mRNA compared to controls, suggesting that this temperature was stressful. *Hsp70* was not induced at the other temperatures. The *hsp70* overexpression at 25°C was unrelated to ammonia concentration so that ammonia-temperature interaction was not found. Our results highlight the influence of temperature and ammonia concentration as crucial environmental parameters for the physiology of *G. pulex*. Developing new and alternative molecular biomarkers will help to monitor and decipher the biological response of natural populations potentially exposed to both stress. Keywords : ammonia, heat shock proteins, freshwater crustacean, TK-TD models

TU156
OA-RESPONSE: Ecosystems in a changing ocean - New CO2 and temperature manipulation system for use in ecological assessment of food web functioning under multiple stressor scenarios
A. Macken, K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment; O. Skogan, L. Xie, A. King, NIVA

The decline in pH and rise in CO_2 manifested through ocean acidification (OA) could potentially result in significant physiological effects on microbes, plankton, and larger organisms, and lead to alterations in biogeochemical cycles and ecosystem function. Concurrent with OA, a variety of other physical and chemical changes are projected for coastal regions that could affect organisms, including increases in the quantity of UV light, increases in sea surface temperature, reduction in salinity, and increases in emerging contaminants e.g. human and veterinary medicines. Phytoplankton and zooplankton comprise the basis of productive coastal and open ocean food webs and provide valuable ecosystem services that humans are socioeconomically dependent on (e.g. animals from fish larvae to baleen whales are dependent on plankton for nutritional needs). The phytoplankton and copepod species (*S. costatum*, *R. baltica*, and *T. battagliai*) that were investigated in terms of response to OA/multiple global change variables are considered vital/keystone to coastal Arctic and Norwegian ecosystems and are the focus of this paper. Two distinct but complimentary systems for the manipulation of seawater CO_2 for use in OA experiments at the "micro-scale" and a more traditional "macro", litre-scale system were developed. For the micro-scale system *T. battagliai* was used as a model organism. There has been documented resilience of copepods to acidification (due to proteins and chitin) and they have a greater capacity to adapt to climate change. However, other factors such as changes in temperature have proven to affect various life stages. In addition exposure to high CO_2 levels can enhance the sensitivity of organisms to thermal extremes. Furthermore, changes in salinity may affect organisms as an independent stressor as well as by altering the bioavailability and in some instances increasing the toxicity of chemicals. The two systems were successfully developed for use in OA experiments, the micro-scale system showed great potential to investigate multiple stressors. In general there is a misconception that zooplankton are insensitive to OA, however, employing more sensitive endpoints like naupliar development and reproduction showed responses vary between life stages. Reproduction and development were greatly influenced by the modification of environmental parameters such as pH, salinity and temperature, which also influenced the toxicity of known toxicants to *T. battagliai*.

TU157

Combined effect of metallic pollutants (Cu and Ag) and temperature on the early life stages of the Mediterranean mussel Mytilus galloprovincialis

K.B. AMMAR, Gironde; M. Banni, Laboratory of Biochemical and Environmental Toxicology; J. CACHOT, EPOC University of Bordeaux

The present work aimed to assess the effect of metallic pollutants (Cu and Ag) exposure along with temperature rise, on early life stages of the Mediterranean mussel Mytilus galloprovincialis. For this, embryo-toxicity assay and RT-qPCR were used to evaluate developmental effectsand gene expression modulation in D-larvae exposed to both thermal and chemical stress. At first, mussel embryos just fertilized were exposed to rising concentrationsof copper (Cu) (0.5 – 500 μg/l) and silver (Ag) (0.1 – 100 μg/l) along with temperature gradient (18, 20, 22 or 24°C) in order to characterize their toxicity and determine the EC50 of each toxicant for the different tested temperatures. Then, increasing concentrations of a Cu-Ag mixture were applied in order to understand and assess the mixture effect at different temperatures. Embryotoxicity was measured after 48h (stage D-larvae) by considering both the percentage of abnormalities and development arrest in D-larvae. Eighteen target genes involved in antioxidant defense, DNA repair, apoptosis, proteolyse, transcription, thermal stress and metalic detoxification were investigated in 48h-developpement larvae. Those were exposed to Cu EC20 (9.6 μg/l), Ag EC20 (2.3 μg/l) and the mixture of (Cu EC10 (6.7 μg/l) +Ag EC10 (1.3 μg/l)) at 3 temperatures (18, 20 or 22°C). The results suggest that the best temperature for mussel larvae development is 18°C (≈ 10% malformations). The rate of malformations increases with increasing temperature to reach 100% at 24°C. Silver has been proved to be more toxic than copper with a half maximal effective concentration (EC50) at 18°C of 6.20 μg/l (5.09 – 6.72) and 18.14 μg/l (13.23 – 18.26) respectively. Temperature seems to increasethe toxicity of these metals as proved with the EC50 obtained at 20°C \nrespectively for Cu and Ag 16.3 μg/l (12.01-16.42) and 3.7 μg/l (2,81-4,07). The higher toxicity of AgCu mixture suggests slightly antagonistic effect ofthe two metallic ions with a synergy factor of 0.68 at 18 ° C. Significant gene transcription modulation was observed for several genes involved in thermal stress (hsp 70), proteolyse (catepsin), DNA repair (p53) and anti-oxidant defense (cat). These changes in gene expression provide new insights to better understand sensitivity of mussels early life stages to combined effects of metallic pollution and temperature rise.

TU158

Did intertidal biota decline after the 2011 Great East Japan Earthquake and Tsunami and the Fukushima nuclear disaster?

T. Horiguchi, National Institute for Environ. Studies / Center for Environmental Risk Research; H. Yoshii, National Institute of Radiological Sciences; S. Mizuno, Fukushima Prefectural Government; H. Shiraishi, National Institute for Environmental Studies

In 2011, 2012, and 2013, in the intertidal zones of eastern Japan, we investigated the ecological effects of the severe accident at the Fukushima Daiichi Nuclear Power Plant that accompanied the 2011 Great East Japan Earthquake and Tsunami. The number of intertidal species decreased significantly with decreasing distance from the power plant, and no rock shell (*Thais clavigera*) specimens were collected near the plant, from Hirono to Futaba Beach (a distance of approximately 30 km) in 2012. The collection of rock shell specimens at many other sites hit by the tsunami suggests that the absence of rock shells around the plant in 2012 might have been caused by the nuclear accident in 2011. Quantitative surveys in 2013 showed that the number of species and population densities in the intertidal zones were much lower at sites near, or within several kilometers south of, the plant than at other sites and lower than in 1995, especially in the case of Arthropoda. There is no clear explanation for these findings, but it is evident that the intertidal biota around the power plant has been affected since the nuclear accident.

Combining exposure and effects models and data for landscape based risk assessment in a regulatory context (P)

TU159

Effect modelling as a bridge from the first tier to the landscape level: An example for mammals

M. Wang, WSC Scientific GmbH / Dept Efate Modelling; M. Foudoulakis, Dow Agrosciences / RSRA ERS; S. Norman, RidgewayEco; N.N. Poletika, Dow Agro Sciences LLC / Field Exposure and Effects Department

In the present study body burden modelling is used to predict potential effects of a pesticide application in mammals. The study is based on a substance with a rather worst-case first tier profile. For parameterisation of the body burden model purpose-designed studies were conducted and the model was validated using data from independent studies, covering different species. The validation demonstrated that the model provided robust but slightly conservative results. Body burden modelling was then conducted considering realistic feeding behaviour obtained from the literature and measured residues in food items. Results indicated a low risk in all focal species. These results were in line with data from large-scale field studies from different crops, which indicated no effects on population abundance or reproduction. This risk assessment exemplarily demonstrates how effect modelling can help to extrapolate results from the lower tier, which only facilitates a limited view of the potential risk since not all factors determining the risk are considered, to a real field situation. The gained knowledge of all factors, including mode of action, individual behaviour or ecology allow a much better understanding of risk and to draw conclusions about the acceptability of a pesticide use with much more certainty.

TU160

Pesticide treatment regimes in landscape based risk assessment

F. Streissl, EFSA / Pesticides Unit; J. Richardson, EFSA / AMU; C. Sinclair, D. Garthwaite, FERA Science Limited

In order to develop landscape based risk assessments it is essential to know all the different stressors, including pesticides, which can potentially impact populations of non-target organisms in the different agricultural landscapes of Europe. The environmental risk assessment evaluates the risk for one single substance at a time. This makes it difficult to apply the recovery principle in the risk assessment. In order to have a correct estimate of the risk to non-target organisms it is essential to link effects to real exposure to pesticides in agricultural landscapes. The European Food Safety Authority (EFSA) recently published a technical report on pesticide application data representative of different crops and different regulatory zones in Europe which can be used as a basis for a future landscape based risk assessment. A total of 394 farms and 2814 fields were surveyed covering the following Northern (Lithuania), Central (Belgium, Netherlands, Poland and United Kingdom) and Southern (Greece, Italy and Spain) zones. Data were collected for arable crops, orchards and grape vines. For 580 fields detailed information on the field margins and surrounding structures was collected and for these fields in some countries detailed historical pesticide usage data, for up to five years, was also collected. The number of products and substance classes applied and the number of spray applications within one growing season varied enormously among the different crops (e.g. 25 spray applications and 39 different formulations in apple orchards versus 5 spray applications and 14 formulations in sugar beet). This suggests that the exposure and hence risk for non-target organisms may vary to a large extent depending on the crops which are grown in different agricultural landscapes. Therefore the development of environmental scenarios including crop relevant treatment regimes are essential for a realistic landscape level risk assessment approach.

TU161

From the first tier to the landscape: How modelling helps to understand the risk

M. Wang, WSC Scientific GmbH / Dept Efate Modelling; M. Foudoulakis, Dow Agrosciences / RSRA ERS; S. Norman, RidgewayEco; N.N. Poletika, Dow Agro Sciences LLC / Field Exposure and Effects Department

In pesticide risk assessment first tier calculations are thought to provide an efficient screening method to detect substances that may need a more detailed evaluation. The first tier risk assessment is usually viewed as a method indicating the level of risk of a given toxic substance. Being based on toxicity and exposure only, other factors that may potentially play an important role in determining the risk to individual animals, are not included. On the other end of the scale, data from large scale field studies may reveal information of the real risk on the landscape level and under real field conditions. Quite often, it is important to understand the results in the field from actual use to reach evidence-based decisions while in some cases it may be difficult for risk assessors to interpret contradicting results. In such cases, effect modelling helps to understand results in the field or why results of the first tier and the landscape scale are contradictory, by making it possible to understand the mechanisms that determine the real risk in a real agricultural setting. In the present study, an example of a substance with a rather worst-case first tier profile is presented, for which information from the field scale indicates a low risk in birds. Body-burden modelling was conducted with fit-for-purpose laboratory studies to understand why no effects were detected on the landscape scale, while the first tier indicated a risk. This evaluation helped to determine the factors that mostly affected the risk and that were not covered by the first tier risk assessment. This example shows how effect modelling can provide a bridge between the first tier and the field scale, and how both regulators and industry can find the evidence and benefit from a better understanding of the mechanisms determining or preventing a risk.

TU162
Models' output on how to combine spatiotemporal scales, biological organizational levels and interactions in environmental risk assessment: A short review.
E. Chaideftou, Benaki Phytopathological Institute / Department of Pesticides Control   Phytopharmacy Laboratory of Toxicological Control of Pesticides; K. Kyriakopoulou, K. Machaira, Benaki Phytopathological Institute
This literature review chronicles the modelling approaches that have been developed for assessing potential risk in the context of environmental risk assessment for pesticides with the aim to reflect the up-to-date outcomes on how to combine spatiotemporal scales, biological organizational levels and interactions in a regulatory context. For this purpose the literature review was carried out by using keywords in all fields of the “Expert search” option “Journals” of ScienceDirect with the formula “environmental risk assessment” and “exposure” and “effect” and “model” and “pesticide”. From 83 publications a thorough full text examination was conducted to include only the publications with consistent information. Therefore only publications that studied and proposed the development, combination and/ or improvement of models to be used in environmental risk assessment were incorporated in this review’s database. Thus data from a corpus of 22 publications from 1997 to 2015 were considered in the results of the current review. Different biological organizational levels were included from individual to populations to community up to landscape. Most models have been initially developed for aquatic organisms and environments though a small minority for soil organisms. Although toxicokinetic parameters have already been mostly developed for pesticides, they were not included in the majority of the proposed models and approaches in the reviewed publications to link exposure with effect. Therefore a clear picture on their contribution to predict dynamic responses over space and time under different exposure regimes cannot be regarded. This applies even for the studies proposing a combination of individual- and population-based models. Population dynamics are considered in either effect or exposure models as well as their combinations. Biological interactions such as predation, competition and density dependence, interactions between different trophic levels, synergism, and also interactions between individuals and their environments from which population dynamics emerge were studied in approximately half of the reviewed database.

TU163
Investigating an ecosystem services framework to advance chemical risk assessment and risk management
S. Marshall, Unilever / SEAC; A.R. brown, University of Exeter; G. Whale, Shell Health / Shell Health; M. Jackson, University of Exeter / Biosciences; M. Hamer, Syngenta / Environmental Safety; A. Solga, Bayer CropScience AG; P. Kabouw, BASF SE; R.W. Woods, ExxonMobil Biomedical Sciences, Inc. / Environmental Toxicology; S. Nadzialek, Albemarle Europe / HSE; L. Maltby, The University of Sheffield / Dpt of Animal   Plant Sciences; M. Galay-Burgos, ECETOC
Our recent review of current EU legislation identified that environmental protection goals tend to be poorly defined, leading to uncertainty in how to achieve such protection. As there is growing interest towards integrating the assessment of ecosystem services (human well-being benefits that flow from natural capital) into decision-making processes well defined protection goals are required to enable risk assessments to be extended to encompass ecosystem services. Recently, the European Food Safety Authority (EFSA) developed a framework to identify ecosystem services potentially affected by (agro)chemicals, set specific protection goals (SPGs) and assess relevant risk assessment schemes. We have investigated the applicability of the EFSA framework for developing SPGs for a wide range of other chemicals using four case studies spanning a range of different emission scenarios and receptor habitats. Based on these case studies, we have discussed and presented approaches by which the EFSA framework’s applicability could be extended to the wider chemical industry. The selected case studies chosen included: oil refinery waste water exposure in estuarine environments; (ii) oil dispersant exposure in aquatic environments; (iii) down the drain chemicals exposure in a wide range of ecosystems (terrestrial and aquatic); (iv) persistent organic pollutant exposure in remote (pristine) environments. A five-step process was followed to identify habitats and ecosystem services potentially impacted by the chemical emissions described and subsequently define possible SPGs in each case study. Case studies demonstrated that it is possible to apply the ecosystem services concept to derive SPGs for a broad range of chemical exposure scenarios. By identifying key habitats and ecosystem services of concern, the approach offers the potential for greater spatial and temporal resolution, together with increased environmental relevance, of risk chemical risk assessments. With modifications including improved clarity on terminology/definitions and further development/refinement of the key concepts, we believe the principles of the EFSA framework could provide a methodical approach to the identification and prioritization of ecosystems and services which are most at risk from chemical exposure.

Recent Developments and Current Issues in Bioaccumulation Assessment (P)

TU164
Using in vitro assay based critical input parameters to evaluating a fish bioaccumulation model for ionogenic organic substances (BIONIC)
s. droge, Utrecht University / IRAS; Y. Chen, Ctgb; J. Hermens, Utrecht University / Institute for Risk Assessment Sciences; J.M. Armitage, University of Toronto - Scarborough / Physical and Environmental Sciences; J. Arnot, ARC Arnot Research & Consulting Inc.
Regulatory and scientific interest in the bioaccumulation and potential ecological risk of ionizable organic chemicals (IOCs) is increasing. Most modeling tools were developed for neutral organic chemicals rather than IOCs. The main objectives of the LRI ECO21 project were to improve methods and data (i.e., membrane-water partition coefficients and biotransformation rates) required to parameterize a mechanistic fish bioaccumulation model for IOCs and to evaluate the performance of key aspects of the model (e.g., gill uptake & biotransformation). *In vitro* biotransformation assays derived from trout liver S9 homogenates were conducted for 50 IOC structures, covering 8 different types of acids and bases. The *in vitro* rates are being compared with *in vivo* and QSAR estimates. New QSARs have been developed for membrane-water partition coefficients for ionized compounds.

TU165
QSAR prediction of human Biotransformation Half-Lives: models development and application
E. Papa, Department of Theoretical and Applied Sciences; A. Sangion, P. Gramatica, University of Insubria / DiSTA
The evaluation of bioaccumulation potential is a key point in the risk assessment of chemicals. However, the quantification of the various processes that characterise bioaccumulation, such as uptake, metabolism and excretion, is challenging due to the extensive costs and the time required to perform bioaccumulation testing. In the last years efforts have been made to generate models based on Quantitative Structure-Activity Relationships (QSARs) in order to predict bioaccumulation-related parameters (i.e. bioconcentration factors, primary biotransformation rate constants and corresponding half-lives) from the molecular structure of compounds. These tools are useful to reduce the experimental impact, and to predict the potential behaviour of existing and not yet synthesised chemicals at a preliminary screening phase. In this poster, we present different QSAR models, which were generated for the prediction of biotransformation half-lives (HL; days) measured in humans, starting from 5 literature data sets and over 1000 organic compounds. The models were developed by paying particular attention to statistical robustness and external predictivity, applicability domain and interpretability. Multiple Linear Regression (MLR-Ordinary Least Squares(OLS) method) and the Genetic Algorithm Variable Subset Selection procedure were performed by using the software QSARINS, and including as independent variables the theoretical molecular descriptors calculated from molecular structures by the software PaDEL Descriptors. These models were applied to predict the potential for human biotransformation of over 1100 Pharamceuticals and Personal Care Products (PPCPs). Additionally, previously published models were applied to predict the biotransformation potential in fish, and the potential behaviuor of the 1100 PPCPs as Persistent, Bioaccumulative, and Toxic compounds (i.e. PBTs). All the data predicted by the aforementioned models were combined by multivariate analysis (Principal Components Analysis, PCA). The analysis allowed for the distinction of the PPCPs slowly biotransformed among those with potential PBT behavior. These PPCPs may be of higher human and environmental concern than PPCPs that are more easily biotransformed. Results from this study show that QSAR models are useful tools not only to fill data gaps but also to refine previous assessments, such as the potential PBT behaviour.

TU166
Determination of thresholds in marine mussels as alternative to

Environmental Quality Standards in marine water: study of bioaccumulation (BAF) and bioconcentration (BCF) factors

A. SIRE, IFREMER / RBE; I. Amouroux, IFREMER / RBEBE

The Water Framework Directive (WFD) establishes Environmental Quality Standards (EQS) in marine water for 34 priority substances. Among these substances, 25 are hydrophobic and bioaccumulable (2 metals and 23 organic compounds). For these 25 substances, monitoring in water matrix is not appropriate and an alternative matrix should be developed. Bivalve mollusks, particularly mussels (*Mytilus edulis, Mytilus galloprovincialis*), are used by Ifremer as a quantitative biological indicator since 1979 in France, to assess the marine water quality. This study has been carried out in order to determine thresholds in mussels at least as protective as EQS in marine water laid down by the WFD. Three steps are defined: - Provide an overview of knowledges about the relations between the concentrations of contaminants in the marine water and mussels through bioaccumulation factor (BAF) and bioconcentration factor (BCF). This allows to examine how a BCF or a BAF can be determined: BCF can be determined experimentally (according to US EPA or ASTM standards), or by Quantitative Activity-Structure Relationship models (QSAR): four equations can be used for mussels. BAF can be determined by field experiment; but none standards exists. It could be determined by using QSAR but this method is considered as invalid for mussels, or by using existing model: Dynamic Budget Model, but this is complex to use. - Collect concentrations data in marine water (C_{water}) in bibliography for those 25 substances ; and compare them with concentration in mussels ($C_{mussels}$) obtained through French monitoring network of chemicals contaminants (ROCCH) and biological integrator network RINBIO. According to available data, this leads to determine the BAF or the BCF ($C_{mussels}$ /C_{water}) with field data. - Compare BAF and BCF values (when available) obtained with various methods for these substances: BCF (stemming from the bibliography, using experimental process), BCF calculated by QSAR and BAF based on field data. This study points out that experimental BCF data are available for 3 substances (Chlorpyrifos, HCH, Pentachlorobenzene). BCF by QSAR can be calculated for 20 substances. The use of field data allows to evaluate 6 BAF: 4 for organic compounds and 2 for metals. Using these BCF or BAF value, thresholds in shellfish can be determined as an alternative to EQS in marine water.

TU167

A reference database for bioaccumulation of organic chemicals in aquatic and terrestrial invertebrates

C.C. Chen, City University of Hong Kong / Department of Architecture and Civil Engineering; D. Kuo, City University of Hong Kong / Architecture and Civil Engineering

Recent advances on the bioaccumulation of organic compounds in fish have been made possible by the availability of high quality bioaccumulation and biotransformation databases. Despite the many bioaccumulation studies made for aquatic and terrestrial invertebrates over the last few decades, and the incorporation of invertebrates into standard bioaccumulation testing protocols, a comprehensive and quality bioaccumulation database of organic compounds in invertebrates has not been available. In order to meet this research need, we have commenced in reviewing and compiling bioaccumulation metrics reported for both soil and benthic invertebrates. Standard bioaccumulation metrics (i.e., BCF, BAF, BSAF, etc.), kinetic rate constants for specific uptake and dissipation processes, details on exposure conditions and experimental setup have been gathered, classified, and archived from primary experimental literature. Target chemicals included both non-polar organic and ionogenic/ionizable organic compounds. Target invertebrate organisms included worms, bivalves, insects, amphipods, isopods, gastropods, decapods, and asteroids, etc. Secondary sources of information – existing bioaccumulation databases or technical summaries – that do not have adequate details and/or show of data points were used only as further sources of reference. To date, a total of over 4000 data entries have been gathered for worms, and approximately 2000 data entries have been collected for other non-worm invertebrates. Individual data entries were reviewed for their quality according to the experimental setup and protocol adopted as well as the data reduction method used, following the approach/scheme outlined by Klimisch et al. (1997) and Arnot & Gobas (2006). Preliminary analysis of the existing data suggested a few interesting trends in the bioaccumulation data. Further scrutiny and analysis of the collected data may reveal meta-level knowledge with respect to bioaccumulation of organic pollutants. The completed version of this database will provide a solid starting point for understanding and modeling the bioaccumulation of organic contaminants in soil and sediment.

TU168

A field monitoring programme to assess the potential for bioaccumulation and biomagnification of a plant protection product in the aquatic and terrestrial environment

F. Kröger, Eurofins Agroscience Services GmbH; S. Lakaschus, A. Lau, Eurofins Agroscience Services Chem GmbH; T. Kellner, RIFCON GmbH Goldbeckstr Hirschberg Germany; M. Münderle, RIFCON GmbH Goldbeckstr Hirschberg Germany / Field Studies; A. Terry, Cambridge Environmental Assessments; A. Lawrence, Cambridge Environmental Assessments / Regulatory Ecotoxicology

As part of the regulatory approval under Regulation (EC) No 1107/2009, a field monitoring programme was conducted following real-world applications to assess the potential for bioaccumulation and biomagnification of a plant protection product in the aquatic and terrestrial environment. The main objective of this presentation is to review what we have learned through direct experience with regards to the sample number requirements, the sampling techniques and the field study design during the conduct of the monitoring programme. The study design was set up to investigate the spatial and temporal fate of the test item throughout terrestrial food chains for soil and crop and aquatic food chains within water and sediment. Large scale field sites (up to 24 ha) were selected according to worst-case conditions, especially in terms of aquatic exposure – e.g. adjacent water bodies. A combined sampling of terrestrial specimens (field soil, crop vegetation, earthworms, small mammals (e.g., common voles and common shrews)) was conducted over periods of up to six months to characterise the magnitude and duration of residues in the relevant terrestrial compartments. To achieve comparable data throughout different matrices and to control spatial variations, replicates with randomized subplots within the treated plot were set up for collecting soil characterisation, soil residue, earthworm residue and crop residue samples from co-located sampling areas. To assess the exposure of the aquatic system in the relevant aquatic compartments, pond water, run-off water, aquatic sediments, aquatic vegetation, macroinvertebrates and fish were sampled from well distributed sampling areas. Sampling was performed from up to 30 replicates and with an abundant amount of samples per event to obtain statistically representative data. Futher in assessing the potential for bioaccumulation and biomagnification, the following matrices were analyzed separately for residues: soil from soil cores, surface and deep burrowing earthworms, oilseed rape plants, oilseed rape leaves, oilseed rape litter, small mammals without gut and gut content, small mammal guts and small mammal gut contents, water, sediment, aquatic macrophytes, macroinvertebrates and fish without gut and/or mucus, fish gut and fish mucus. To be able to compare the residues of different matrices, soil and plant residues were normalized for organic carbon; residues of earthworms and small mammals were normalized to lipid content.

TU169

Results and interpretation of a field-scale bioaccumulation and biomagnification monitoring programme

A. Lawrence, Cambridge Environmental Assessments / Regulatory Ecotoxicology; A. Terry, Cambridge Environmental Assessments; F. Kröger, Eurofins Agroscience Services GmbH; S. Lakaschus, A. Lau, Eurofins Agroscience Services Chem GmbH; T. Kellner, RIFCON GmbH Goldbeckstr Hirschberg Germany; S. Taylor, Cambridge Environmental Assessments; M. Münderle, RIFCON GmbH Goldbeckstr Hirschberg Germany / Field Studies

Bifenthrin was recently approved as an active substance, in accordance with Regulation (EC) No 1107/2009, with a confirmatory data requirement to submit: "*a monitoring programme to assess the potential for bioaccumulation and biomagnification in the aquatic and terrestrial environment*". No guidelines are available for conducting monitoring programmes to assess the potential for bioaccumulation and biomagnification in the environment. Direct spray studies were conducted in North Germany to determine whether bioaccumulation or biomagnification occurred following realistic exposure of aquatic and terrestrial systems to bifenthrin. The investigations were designed to represent the full proposed GAP for bifenthrin in the EU, which includes application to early and mature crops, and to address worst-case scenarios in terms of exposure routes in the environment. In the terrestrial environment, appropriate food chains for soil (soil, earthworm, small omnivorous and insectivorous mammal) and crop (crop, small herbivorous mammal) were sampled. For the aquatic environment, food chains based on water and sediment with aquatic macroinvertebrates and fish were sampled. The mitigation measures employed to ensure acute and chronic safety to aquatic organisms (20 m no-spray buffer and 90% drift reducing nozzles) ensured that bifenthrin residues in the aquatic systems were low, even following purposefully exaggerated irrigation. Detectable residues in fish surface mucus samples demonstrated the presence of bifenthrin in the aquatic system. Despite exposure, however, there was no evidence for bioaccumulation or biomagnification of bifenthrin in aquatic systems. Residues in small mammals were low. Shrews had lower residue levels than earthworms. Other small mammals likely to consume earthworms also had residues below the levels in earthworms and crop, and significantly decreased over time. Residues in voles, which feed on vegetation, were also low and dissipated rapidly. These investigations, involving real-world applications of bifenthrin according to proposed GAP, demonstrated that bifenthrin does not bioaccumulate or biomagnify in aquatic food webs, nor does it biomagnify at the small mammal trophic level in terrestrial systems.

TU170

Application of equilibrium and mechanistic models to facilitate the interpretation of a terrestrial field bioaccumulation study

J.M. Armitage, University of Toronto - Scarborough / Physical and Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting / Department of Physical Environmental Science; F. Kröger, Eurofins Agroscience Services GmbH; A. Lau, S. Lakaschus, Eurofins Agroscience Services Chem GmbH

As part of the regulatory approval of bifenthrin as an active substance under

Regulation (EC) No 1107/2009, a monitoring programme to assess the potential for bioaccumulation and biomagnification in the aquatic and terrestrial environment following field application was required. The main objective of this presentation is to demonstrate how equilibrium-based and mechanistic bioaccumulation models can facilitate the interpretation of monitoring data collected during such studies. The focus of the modelling is on the bioaccumulation of bifenthrin by earthworms (e.g., *Lumbricus terrestris*, *Aporrectodea caliginosa*). The primary motivation for application of bioaccumulation models was the observed earthworm-soil concentration ratios, which were much larger than expectations based on the properties of bifenthin (hydrophobicity, potential for biotransformation) and previous laboratory-based studies. A key confounding issue with the field data was that the soil concentrations were based on 10 cm deep (homogenized) cores, whereas the chemical was likely distributed primarily in the upper soil layers. For *L. terrestris*, equilibrium-based and mass balance bioaccumulation modelling supports the hypothesis that this species is exposed primarily via ingestion of crop litter, which exhibited larger concentrations of bifenthrin than the bulk soil at the surface and the concentrations reported for the homogenized 10 cm profile. For this reason, it is important to collect data characterizing the properties of the leaf litter over time (e.g., seasonal differences) as well as measuring chemical concentrations. For *A. calignosa*, the modelling supports the hypothesis that concentrations of bifenthrin in material ingested by these earthworms are substantially elevated compared to the measured concentrations for the homogenized 10 cm soil profile. Collectively, the calculations suggest that the measured concentrations of bifenthrin for the homogenized 10 cm soil profile are not representative for calculating biota-soil accumulation factors (BSAFs) and characterizing the bioaccumulation potential of bifenthrin in the field. In addition to facilitating the interpretation of the data collected during the field campaign, the bioaccumulation modelling conducted here provides a clear direction for additional empirical studies (i.e., hypothesis testing) aimed at characterizing the bioaccumulation potential of organic chemicals in agricultural settings.

TU171

Development of Multibox-AQUAWEB Model for Prediction of Trophic Magnification Factors Influenced by Spatial Concentration Gradients, Species Migration, and Field Sampling Design

J. Kim, Dow Corning Corporation / Health and Environmental Sciences; F. Gobas, Simon Fraser University / School of Resource and Environmental Management Faculty of Environment; J.A. Arnot, ARC Arnot Research & Consulting / Department of Physical Environmental Science; D.E. Powell, Dow Corning Corporation / Environmental Sciences; R.M. Seston, Dow Corning Corporation / Health and Environmental Sciences; K.B. Woodburn, Dow Corning Corporation / HES

Trophic magnification factors (TMFs) integrate all routes of chemical exposure and ecosystem processes to evaluate the bioaccumulation behavior of chemicals in food-webs. However, current food web bioaccumulation models do not consider spatial heterogeneity, species migration, and field sampling design. Thus, a Multibox-AQUAWEB (MBAW) model was developed to calculate chemical concentrations and TMFs by including the aforementioned processes to the existing AQUAWEB model. The MBAW model was coded as a Microsoft Excel 2013 workbook containing three worksheets for input parameters, four worksheets for calculations based on the mass balance equations, and one worksheet for output. The MBAW model allows users to define numerous compartments to specify vertical and/or horizontal concentration gradients in an aquatic system. The model also requires the users to define species composition, structure, and trophic dynamics of the aquatic food web. For species migration, the users can define the fraction of time that each species occupies a particular compartment. This input specifies the distribution of a species to a certain area and the degree to which a species may be present in multi-dimensional space. The model also provides the users with the option to specify the "sampling" location of each species by identifying the compartment(s) from which the species will be collected. This feature provides a method for investigating the effect of sample collection location on the TMF in situations where spatial differences in concentrations exist. Using the inputs and mechanisms in the model, the MBAW model calculates the steady-state (whole body wet weight and lipid-equivalent) chemical concentrations in species in each compartment. Based on the predicted concentrations, TMFs are calculated as the antilog of the linear regression slope of log-transformed lipid equivalent concentrations regressed on trophic position. The TMF can be calculated for various sampling scenarios to investigate the effect of sampling design on the determination of the TMF in areas with significant spatial concentration gradients. The MBAW model provides guidance on both the conduct and interpretation of field bioaccumulation studies and highlights the need for development of detailed protocols for field bioaccumulation studies in aquatic food-webs.

TU172

Development and testing of a physiologically based toxicokinetic model of the rabbit (Oryctolagus cuniculus) using the PK-Sim® software suite

H.E. Hermes, P.D. Mavroudis, Bayer Technology Services GmbH; T. Preuss, Bayer CropScience / Environmental Modelling; L. Goerlitz, Bayer Technology Services GmbH

Measuring the concentration and effect of pesticides on all affected species under all conceivable scenarios is not feasible. Therefore standard laboratory species are tested and the endpoints are translated to focal species for environmental risk assessment. Modeling is becoming increasingly important for evaluating the consequences of pesticides in untested scenarios. Acute toxic effect predictions require knowledge of the relevant compound concentrations in target organs. Physiologically based pharmacokinetic (PBPK) modeling is a well-established methodology for predicting target tissue concentrations based on the absorption, distribution, metabolism and excretion properties of drugs. The approach facilitates the extrapolation of drug PK knowledge gained in pre-clinical species such as rats and dogs to predict the drug PK in humans. For toxic substances, PBPK modeling is renamed physiologically based toxicokinetic (PBTK) modeling. In the widely used PK-Sim® software suite, physiologically based models which enable PBTK modeling are available for typical clinical species but not for the species such as small mammals which are typically considered for risk assessments. Rabbits are the herbivorous field species for which sufficient data is available to develop and validate a physiologically-based model. In this poster we give details of the rabbit model we have developed and implemented in the PK-Sim® software suite. We show that the model can describe the concentration of drugs in the plasma and different organs of the rabbit. In addition, we illustrate how the physiologically based modeling approach can be used to translate toxicokinetic knowledge from one species to another, for example, from a laboratory rat to a rabbit.

TU173

Transfer kinetics of dissolved perfluorooctanesulfonate (PFOS) to a marine sandworm species

T. Sakurai, National Institute for Environmental Studies / Center for Environmental Risk Research; J. Kobayashi, Prefectural University of Kumamoto; N. Ito, S. Serizawa, H. Shiraishi, T. Yabe, National Institute for Environmental Studies; Y. Ishii, Tokyo Metropolitan Research Institute for Environmental Protection; N. Suzuki, National Institute for Environmental Studies

We determined the respiratory uptake and depuration kinetics of perfluorooctanesulfonate (PFOS) in a polychaete sandworm species, *Perinereis wilsoni*, and compared them with those reported for other aquatic animals. The breadth of taxonomic groups covered by bioaccumulation kinetic studies is still limited. Thus the basis for species-extrapolation of bioaccumulation kinetics is yet to be established. Bioaccumulation of perfluoroalkyl acids (PFAAs) including PFOS in aquatic organisms is of interest because consumption of seafood was suggested as a major source of human exposure to PFAAs. Polychaete species in general represent an important path of chemicals present in the marine coastal environment to higher organisms. A 7-day exposure period was followed by a 9-day depuration period. Sandworms were held in cylindrical containers packed with gravels. The water level was controlled daily to mimic the tide. During the depuration period, the sandworms were fed commercial fish food. We used filtered (0.1 μm) natural seawater kept at about 17.1 °C. Sandworms and seawater were regularly sampled and analyzed for PFOS. Wet mass of the sandworms were monitored by weighing randomly selected individuals. The oxygen consumption rate of the sandworm was also measured. The PFOS depuration rate constant, respiratory uptake rate constant, and respiratory absorption efficiency for the sandworm were estimated by fitting the measured concentrations to a first-order kinetic model. The PFOS concentrations in seawater averaged 30 ng/L during the exposure period of the exposure treatment and were negligibly low in the control treatment and the depuration period of the exposure treatment. The PFOS concentrations in the sandworm samples from the exposure treatment increased during the exposure period and decreased afterwards. The estimated value of the PFOS depuration rate constant (0.050 d^{-1}) was similar to those reported for a freshwater oligochaete and for the whole body of several fish species, but one order of magnitude lower than that for an oyster species. Although the value of the PFOS respiratory uptake rate constant (32 L kg-wet^{-1} d^{-1}) was in the same range as for the whole body of several fish species and the oyster, the value of the respiratory absorption efficiency (0.13) was generally higher than those estimated for several fish species. These results suggested a more efficient respiratory uptake of PFOS by the sandworm than by fish.

TU174

Bioaccumulation of Selenium through the food chain: water - Lemna minor - Pomacea paludosa

T. Hoang, Loyola University Chicago / Institute of Environment and Sustainability; A. Ahmed, Loyola University Chicago

Selenium (Se) has been used as a fungicide in sugar cane growth in South Florida for many decades. The long-term use of Se in these environments has led to an increase in Se concentrations in the soil. Under the Comprehensive Everglades Restoration Plan, thousands of acres of agricultural lands will be flooded to create wetland habitats and water reservoirs. Flooding lands will result in Se desorption from soils to water and would affect aquatic organisms. Aquatic plants such as *Lemna minor* (duckweed), inhabitants of these systems, can accumulate Se which then can be transferred via predation to higher trophic levels. The objective of this study is to study how Se transfers through different levels of the food chain (water-duckweed –*Pomacea paludosa* (Florida apple snail). Under standard laboratory conditions, duckweed was exposed to three different concentrations of Se (100 μg/L, 500 ug/L, 1000 ug/L) for 2 weeks. Apple snails were fed with Se contaminated duckweed for 28 days. During the course of the study, apple snails and duckweed were collected at different time intervals for Se analysis. This study found that Se was bioaccumulated from water to duckweed and apple snails. Se concentrations in duckweed increased with Se treatment concentration and ranged from 1 mg/kg dw (control) to 431 mg/kg dw (T3). Concentration of Se in the snail soft tissue (food + viscera) increased with increasing Se duckweed concentration and ranged from 0.77 mg/kg dw (control, day 0) to 142 mg/kg dw (T3, day 21). In general, Se concentration in apple snails increased in the order of shell, food, and viscera. Se concentration in the snail soft tissue also increased with exposure time. Results of this study are in agreement with the results of other studies with copper and zinc and apple snails.

Challenges in environmental read-across and grouping of substances - when fate, bioaccumulation and ecotoxicological properties are similar enough? (P)

TU175

A comparison of the toxicity of hindered phenols and substituted phenyl amines to terrestrial plants and invertebrates in a sandy soil

J. Princz, E. Ritchie, S. Howe, Environment Canada / Biological Assessment and Standarization Section; R.P. Scroggins, Environment Canada / Biological Methods

A research project was initiated by Environment Canada's Biological Assessment and Standardization SEction (BASS) as part of the Canadian Federal Government's Chemicals Management Plan (CMP), to assess the toxicity and bioaccumulation potential of two groups of organic compounds to terrestrial organisms. The groups of organic compounds (hindered phenols and substituted phenyl amines) were selected based on the expectation of partitioning primarily to soil, varing availability in soil, and based on limited effect data in general. Two representative chemicals from each group were selected for toxicity testing with the intention of using the empirical data for read-across and to fill data gaps within the groups for subsequent risk assessment purposes. The hindered phenol group was represented by 3,6-di-tert-butylphenol (CAS 128-39-2) and 2,2'-thiodiethylne bis[3-(3,5-di-tert-butyl-4-hydroxyphenyl)propionate] (CAS 41484-35-9), while N-phenyl-o-phenylene diamine (CAS 534-85-0) and N,N'-di-2-naphthyl-1,4-phnylenediamine (CAS 93-46-9) were selcted to represent the substituted phenyl amines group. The inherent toxicity of the test substances were assessed through invertebrate (*Folsomia candida* and *Eisenia andrei*) reproduction and plant (*Trifolium pratense* and *Elymus lanceolatus*) definitive tests, using Environment Canada's standardized soil test methods. Effects on *E. andrei* reproduction were then evaluated in order to select a single chemical from each group for bioaccumulation tests. The generated data, with accompanying exposure characterization will be presented, with an evaluation of the read-across potential of these substances to environmental risk assessments.

TU176

How to group organotin compounds in view of their regulatory assessment under REACH?

N.M. Deleebeeck, N. Schraepen, M. Messiaen, S. Bergeret, ARCADIS / Environment; F. van Broekhuizen, A. Muller, National Institute for Public Health and the Environment RIVM

Organotin compounds represent a group of organometallic compounds which has attracted regulatory attention several times already. Due to a combination of known use patterns, expected/demonstrated fate and behaviour in the environment, and intrinsic hazards, this regulatory attention has not diminished – at the time of writing this abstract, the following activities have been identified under REACH: there are two restrictions (one on organotin compounds in general, and one substance-specific), four organotin substance have been included in the candidate list for inclusion in Annex XIV of REACH (authorisation list), four organotins are on the CoRAP list (Community Rolling Action Plan) for substance evaluation, harmonised classification has been proposed/agreed on for various organotin compounds, and finally, a number of other evaluative activities have been identified in the PACT (Public Activities Coordination Tool), such as hazard evaluations (PBT/vPvB assessment, assessment of endocrine disrupting properties), risk management option analyses, etc. All these regulatory/evaluative actions are now being follow up on a one-by-one basis. To come to a more efficient approach, it was considered necessary to investigate how organotin compounds may be grouped for further evaluation. Based on the currently available information in the +30 REACH registration dossiers for organotin compounds, an effort was made to map grouping and read across actions as proposed by industry. Specific attention was given to the information used to justify grouping and read across. Then, taking into account international guidance on grouping of chemicals in general and more specifically of organometallics (e.g. ECHA, OECD), as well as previous work on grouping of organotin compounds (e.g., OECD CoCAP), a framework has been proposed to evaluate stepwise whether or not an organotin compound can be included in a certain category of organotins for read across purposes for a specific (type of) endpoint. This framework indicates what information should minimally be available or be generated to allow this evaluation. Further, it is investigated to what extent information on uses can – on top of all other information – be applied to evaluate which risk management measures (if any) would be required to guarantee safe use of groups of organotin compounds. This project therefore contributes to reaching the objectives as put forward in the SVHC Roadmap 2020.

TU177

Towards the Environmental Read-Across Assessment Framework

A. Nyman, European Chemicals Agency (ECHA); U. Helminen, ECHA-European Chemicals Agency; D. Hirmann, K. Prevedouros, European Chemicals Agency; B. Versonnen, European Chemicals Agency / Evaluation; G. de Seze, European Chemicals Agency

REACH is a Regulation of the European Union, adopted to improve the protection of human health and the environment from the risks that can be posed by chemicals, while enhancing the competitiveness of the EU chemicals industry. It also promotes alternative methods for the hazard assessment of substances in order to reduce the number of tests on animals. Grouping of substances and read-across is one of the most commonly used alternative approaches for filling data gaps in registrations submitted under the REACH Regulation. This approach uses relevant information from analogous 'source' substances to predict the properties of 'target' substances. During dossier evaluation and testing proposal examination (REACH Regulation Title VI), the justification for the grouping of substances and read-across provided by registrants is assessed by ECHA to check whether it fulfils the legal requirements. To allow transparency and consistency of the read-across assessments, ECHA published a human health read-across assessment framework in 2015 and is now developing the Environmental Read-across Assessment Framework (ENV RAAF). It aims at structuring and codifying expert judgement of complex scientific questions on the critical aspects of verifying the justification provided by the registrants. Here we present the ENV RAAF which is divided into four sequential steps. First, the assessor performs an administrative check to make sure that a meaningful scientific assessment can be carried out. Then, the provided documentation will be assessed with regards to data quality and the hypothesis or rationale will be verified. All of the information provided for the target and source substances should be considered to enable a robust verification of the hazardous properties of the target substance when comparing them to the source. When concluding the assessment, it is kept in mind that the results of the study(ies) provided for the source substance(s) are also used for classification and labelling and/or risk assessment of the target substance. Therefore, it needs to be ensured that the hazardous properties of the target substance are not underestimated. Finally, the assessment and its outcome are documented. Application of the ENV RAAF should result in a structured step-wise assessment, consistently performed between assessors, that recognises the strengths of the read-across and identifies possible shortcomings in documentation, scientific reasoning and/or supporting evidence.

TU178

Weight of evidence approach to assess the acute aquatic toxicity of GTL solvents relative to other hydrocarbon solvents

C. Hughes, Shell International Limited / Shell Health; C.V. Eadsforth, Shell International / Shell Health; S. Harris, Shell International Limited / Shell Health

Hydrocarbon solvents are petrochemicals used in a wide range of industrial and consumer applications globally. These products consist of many different hydrocarbon constituents and are described as UVCB substances (substances of Unknown or Variable composition, Complex reaction products or Biological materials). They are most commonly derived from the processing of crude oil, but other varieties, such as synthetic 'isoparaffins' and solvents derived by the Fischer-Tropsch, or 'Gas-to-Liquid' (GTL) process, also exist. Although different solvents may share similar performance properties, their composition varies depending on the manufacturing process and they are regarded as different substances under REACH. In order to assess the relative aquatic toxicity of GTL solvents compared with other hydrocarbon solvents a range of screening methods have been used. These included testing of water-accommodated fractions (WAFs) using solid-phase micro-extraction (SPME) combined with gas chromatography (GC) analysis, MICROTOX^{TM} and DAPHTOXKIT F^{TM} assays, and toxicity predictions using the PETROTOX model. Results were compared with compositional information for each of the substances and available experimental data from GLP compliant acute aquatic toxicity studies, conducted under OECD guidelines. The results of the screening tests suggested that acute toxicity of GTL Solvents is dependent on hydrocarbon chain length, similar to dearomatised and isoparaffinic hydrocarbon solvents. The white spirits were significantly more toxic based on screening data, which was expected based on the presence of aromatic constituents. On the basis of the experimental screening methods applied, the two most sensitive approaches for detecting toxicity of the various products are SPME-GC and the DAPHTOXKIT F^{TM} test kit, whereas the MICROTOX^{TM} assay is the least sensitive. The PETROTOX calculations predicted a similar relationship with chain length, but were generally more conservative than the experimental data. Overall, through the use of a range of screening methods in a weight of evidence approach, the acute aquatic toxicity of GTL solvents was successfully determined relative to other types of hydrocarbon solvents.

TU179

Environmental risk assessment of natural complex substances: needs for methodology adjustments

l. geoffroy, S. ANDRES, INERIS / Toxicological Ecotoxicological Assessment of chemical Substances

Natural complex substances (NCS) are under the scope of European regulations on chemicals (Biocides, PPP, REACH, CLP…). For example under REACH regulation NCS are considered as substances, either mono-, multiconstituent or UVCB. In most cases however, NCS can be considered as UVCB, hydrophobic and volatile substances. The objective of the study is to identify difficulties in environmental hazard and risk assessment of these substances and propose methodology adaptations for these chemicals. Two strategies are generally envisaged for their evaluation: one considering the NCS as a "substance" as a whole or taking its "constituent" as a basis of the assessment. The approach “substance” shows the advantage to consider the effects of all the constituents of the mixture without these needing to be totally identified. For inconvenience, certain required data have no meaning for a UVCB such as the solubility, the Kow, the bioaccumulation which are parameters intrinsically appropriate to each of the constituents. Other data can be obtained by testing the substance directly. The “constituent” approach requires an important effort for the characterization of the NCS. Besides, the addition of the effects of each constituent is not necessarily equal to the effect of the mixture as such. The approach by constituent and the characterization of these allows the use of alternative methods as the approach QSAR, by congener or category and thus the read-across between constituents. Under REACH regulation, for the tonnage band greater than 10 T/year, environmental exposure and risk have to be assessed. In this case, for environmental exposure, constituents have to be taken into account, the environment acting as a filter, the UVCB as such does not exist. It can be then decided to consider the predicted environmental concentration (PEC) of the most soluble of known constituents and to compare it with the predicted no effect concentration (PNEC) of the substance. This approach can be relatively conservative and can be refined in higher tier assessment. An example of this assessment is presented to illustrate the methodology.

TU180

Data Availability of REACH Registrations: Adaptation of Information Requirements for High Tonnage Chemicals

A. Mueller, RWTH Aachen University / Chemicals and Product Safety; D. Sittner, Federal Institute for Risk Assessment / Chemical and Product Safety; A. Springer, Federal Institute for Risk Assessment / Chemicals and Product Safety; H. Herrmann, Department of Environment and Energy of the City of Hamburg; U. Herbst, Federal Institute for Risk Assessment / Chemicals and Product Safety; F. Kaßner, Umweltbundesamt / Federal Agency of Environment / IV Chemicals; A. Schulte, Federal Institute for Risk Assessment / Chemicals and Product Safety

According to the REACH Regulation (EC) No. 1907/2006 chemicals produced, marketed or used within the European Union have to undergo a registration process, wherein the registrants have to provide information on hazards presented by the substances and assess potential risks. The standard information requirements defined in Annexes VII to X of the regulation may be waived or adapted by the registrants if adequate documentation and justification according to criteria specified in Annexes VII to XI are provided. To evaluate the availability of ecotoxicological data in registration dossiers of high tonnage substances (1000 tpa or more) and their compliance with the REACH Regulation, the Federal Institute for Risk Assessment (BfR) in cooperation with the Federal Environment Agency (UBA) developed a systematic web-based screening scheme. In total, 1932 dossiers were checked for selected environmental endpoints such as biotic and abiotic degradation, bioaccumulation and ecotoxicity. A remarkable high rate, 43% to 82 % depending on the endpoint, of the evaluated dossiers included waiving or adaptations from the standard information requirements such as read-across approaches. The assessment of the appropriateness of waiving and adaptations were part of a follow-up project. Herein, it was evaluated whether the given justifications were in accordance with the criteria set out in the respective REACH Annexes. Altogether 335 cases were evaluated for all environmental endpoints and categorized as “formally compliant” and “formally non-compliant” referring to the formal correctness, “obviously compliant” and “obviously non-compliant” indicating compliance with regards the content or “complex”. Thereby, 31 % of all cases were classified as “formally compliant” and 2 % as “obviously compliant”, whereas 12 % were assigned to “obviously non-compliant” and 19 % to “formally non-compliant”. However, 35 % were not concluded and remained as “complex”. Read-across approaches were most frequently used as justification for waiving. The results will show the frequency and pattern of waiving/adaptation approaches for the environmental endpoints. Besides this general overview, specific problems regarding the application of the REACH Regulation were identified and their relevance with regard to remaining data gaps will be discussed.

Environmental risk assessment of chemical mixtures: the steps ahead (P)

Addressing combined toxicity in the environmental risk assessment of inorganic UVCBs: some case studies

K. Oorts, F. Verdonck, F. Iaccino, ARCHE; V. VEROUGSTRAETE, Eurometaux / EHS; H. Waeterschoot, Eurometaux

There is a clear need to include a generic approach to address combined toxicity when assessing multi-metallic substances such as inorganic UVCBs (iUVCBs). Because the variability in composition is generally too arge, it is not possible to identify a set of samples that would be representative and conservative for the hazard identification of the iUVCB and hence experimental testing is not feasible. For this reason, the iUVCBs risk assessment is conducted based on the assumption that the toxicity is driven by the toxicity of their constituents, resulting in parallel risk assessments of the constituents. In a conservative approach, each constituent of the substance is assessed based on its maximum concentration and its most severe chemical speciation. Upon ECHA’s request, registrants of iUVCB intermediates committed to improve the the combined toxicity assessment part of their REACH registration dossiers. However, an appropriate standard approach to address the combined toxicity of inorganic constituents in a regulatory framework is still missing: most standard approaches yield indeed over-conservative results such as risk scenarios at natural background concentrations when several metals are combined. Therefore, a generic tiered approach has been recently developed for the environmental risk assessment of iUVCBs. This approach starts from the standard concentration addition evaluation based on summation of the PEC/PNEC ratios of the individual constituents and includes several options for refinement of this standard approach, e.g. taking into account bioavailability, using msPAF approaches or assessment per trophic levels. In addition, screening methods for evaluating the relative importance of data poor constituents are included in the overall approach. This poster presents the results of this tiered approach for addressing the combined toxicity in a constituents-based environmental risk assessment for some representative iUVCBs.

TU182

Toxicity and bioavailability of lubricants and their additives in the aquatic environment

J. Hartmann, Shell International / Shell Health Risk Science Team; C.V. Eadsforth, Shell International / Shell Health; J. Hermens, Utrecht University / Institute for Risk Assessment Sciences; T. Halmans, Shell Global Solutions International / Anakytical Department; J. Worden, Shell International / Shell Health Risk Science Team; J. Haftka, Utrecht University / Institute for Risk Assessment Sciences

For the purpose of communicating environmental hazard via material safety data sheets and product labels, lubricants have to be classified according to their toxicity to the aquatic environment. In line with European Classification, Labeling and Packaging guidelines and GHS classification guidelines, the classification of mixtures should primarily be based upon the available test data on the mixtures as a whole or on similar mixtures. However, in those cases where these data are missing, the classification should be based on calculation (i.e. the GHS summation method) using those ingredients classified for the particular hazard. As experimental data on the aquatic toxicity of lubricants are often not available, hazard assessment of these products is regularly based upon the toxicity of the individual hazardous ingredients, the additives. Fully Formulated Lubricants (FFLs) were tested in screening tests with crustaceans (*Daphnia magna*), algae (*Selenastrum capricornutum*) and bacteria (*Vibrio fischeri*). The test results were then compared with classifications derived from applying the summation method. It is suggested that the additives might not be bioavailable to the aquatic ecosystem due to their incorporation into the lubricant (OECD, 2004). An overestimation of the aquatic toxicity of the final product may be due to a reduction in the bioavailability of the highly toxic additives as a consequence of partitioning into the lubricant base oil. To test this hypothesis, toxicity data were generated (from water accommodated fractions (WAFs)) on the additive packages containing the toxic components on their own and in the presence of base oil as the FFLs.

TU183

What do effect-based tools need to capture to support water monitoring?

W. Busch, Helmholtz centre for environmental research - UFZ / Bioanalytical Ecotoxicology; M. Krauss, T. Schulze, Helmholtz centre for environmental research - UFZ / EffectDirected Analysis; R. Kühne, Helmholtz Centre for Environmental Research UFZ; S. Schmidt, C. Lange, Helmholtz Centre for Environmental Research UFZ / Bioanalytical Ecotoxicology; J. Kuhlmann, Helmholtz Centre for Environmental Research UFZ; N. Munz, J. Hollender, Eawag / Environmental Chemistry; R. Altenburger, UFC Centre for Environmental Research / Bioanalytical Ecotoxicology

Environmental quality monitoring of water resources is challenged with providing the basis for safeguarding the environment against adverse biological effects of anthropogenic chemical contamination from diffuse and point sources. While current regulatory efforts focus on monitoring and assessing a few legacy chemicals, due to progress in analytical techniques many more anthropogenic chemicals are and will be detected in our aquatic resources. Assessing this type of exposure information based on available standard approaches from single chemical prospective risk assessment leads inevitably to indication of risk in most surface water bodies (Malaj et al. 2014, Stehle and Schulz 2015). However, exposure to neither individual chemicals nor mixtures does necessarily translate into adverse biological effects. As an alternative to generic assessment approaches effect-based monitoring approaches are suggested (Escher et al. 2014). To become a credible complement to chemical monitoring information we need, however, better understanding of the capabilities and gaps of available effect-based tools (EBT). In this work we therefore undertake to (i) compile organic contaminants detected in freshwater monitoring studies, (ii) provide a synopsis on the mode-of-action knowledge available for the detected compounds to map against available EBTs coverage, and (iii) utilise a hazard identification approach to identify priority compounds for effect-based monitoring. From our work it emerges that chemical occurrence in European freshwaters seems to be highly variable in composition and relative abundancies. Further, while we are substantially limited in our mode-of-action knowledge we can already identify major gaps in coverage of potential effect qualities when relying on established EBTs. Finally, we suggest a list of organic compounds that could serve as a reference list for EBT validation studies.

TU184

Attempt to apply the WHO/IPCS framework on assessment of combined exposure to multiple chemicals to regulatory environmental risk assessment of chemicals

K. Yamazaki, Env Health Dep., Ministry of the Environment / Environmental Health Department

Environmental risk assessment for regulatory objectives is in general conducted on a chemical-by-chemical basis. Under the limited resources, considering mixtures assessment for all of the chemicals under the regulatory environmental risk assessment will not be effective nor practical. High-priority chemicals groups should be identified efficiently. WHO/IPCS proposed a framework adopting tiered approach for assessment of combined exposure to multiple chemicals. We have been conducting attempts to apply this framework to consider multiple chemicals in the present practices on environmental risk assessment of regulatory objectives. Concentration of chemicals in the ambient environment (air and water), which can be obtained through monitoring programs by national and local governments as well as academic studies, can provide information on combined exposure to multiple chemicals. Concerning hazard to the environment, our tentative focus is on "conventional ecotoxicity" to typical aquatic organisms. In order to examine the applicability of the framework, case studies for certain groups of chemicals have been implemented. Target groups of chemicals have been identified considering structural similarity, modes of action and co-existence in the ambient water. Updated situation of the case studies will be presented at the Annual Meeting.

FRAM - The Centre for Future Risk Assessment and Management Strategies at the University of Gothenburg

T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences; J. Coria, L. Gipperth, University of Gothenburg / School of Business Economics and Law; M. Hassellov, University of Gothenburg / Department of Marine Sciences; E. Kristiansson, Chalmers University of Technology / Department of Mathematical Statistics; S. Molander, Environmental Systems Analysis, Chalmers University of Technology / Energy   Environment; P. Rendahl, University of Gothenburg / Department of Business Economics and Law; D. Slunge, University of Gothenburg / Centre for Environment and Sustainability; P. Tiselius, University of Gothenburg / Department of Biological and Environmental Science; T. Sterner, University of Gothenburg / Department of Business Economics and Law

Chemicals are typically assessed and managed one after another for their environmental risks, based on the notion that the each chemical is the only toxic substance present in an otherwise pristine environment. It is becoming increasingly clear that this strategy is a major shortcoming of even modern regulatory frameworks such as REACH, as it is a precarious oversimplification of reality, in which dozens or even hundreds of chemicals are present at any given time and location in the environment. \nFailing to account for the presence of chemical cocktails in the environment is particularly problematic because scientific evidence shows that the toxicity of a mixture usually exceeds the toxicity of each individual compound and that small, individually non-toxic concentrations might add up to a severe toxicity of the overall cocktail. Chemicals in the environment are thus a typical case of the "tragedy of the commons": even if the ecosystem impact of each individual chemical emission might be acceptable, their combined effects might not. The failure to set boundaries for the total chemical emission from multiple chemicals, sources and activities erroneously implies an open, infinite ecosystem. This obviously wrong assumption is the Achilles heel of current chemical regulation. It is not sufficient to ensure that the actions of an individual company, authority or consumer are on an acceptable level - it is their joint impact that matters for ensuring sustainable chemical governance. \nThe FRAM center is therefore set-up to provide an organizational structure for work towards defining safe local, regional and global boundaries for chemical pollution that protect ecosystem services against the impact of the totality of chemical emissions and exposures. It will develop policy instruments for the fair sharing of the available common emission space. FRAM will in particular explore how flexible and scientifically sound chemical management systems can be established in middle- and low-income countries. The center is set up at the University of Gothenburg and is run by an interdisciplinary group of environmental scientists (ecotoxicology, ecology, environmental chemistry, life cycle assessment and systems analysis), environmental economists, legal and tax experts as well as political scientists. Initial funding is provided for a duration of seven years, from 2016 to 2023.\n\n

Effect-based screening of whole blood to evaluate complex   chemical exposure of sea turtle populations in the Great Barrier Reef

G. Dogruer, RWTH Aachen University / Department of Ecosystem Analysis; J. Tang, The University of Queensland / National Research Centre for Environmental Toxicology Entox; I. Bell, Department of Environment and Heritage Protection, Threatened Species Unit, Townsville, Australia; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis; C. Hof, Species Conservation, World Wildlife Fund for Nature, Australia; C. Gaus, The University of Queensland / National Research Centre for Environmental Toxicology Entox

The globally endangered green turtle *Chelonia mydas* occurs in coastal and estuarine environments, where they can be exposed to a wide range of known and unknown chemicals. Target analyses are poorly suited to evaluate such exposure or associated risks. The objective of this study was to validate and test the application of bioanalytical screening approaches to investigate the combined effects of chemical mixtures in whole blood. We used green turtles from three different habitats in the Great Barrier Reef to assess whether their chemical exposure differs. Blood samples were collected from turtles foraging in nearshore areas associated with agricultural activities (Upstart Bay), industrial sources and urban runoff (Cleveland Bay), and a relatively pristine offshore site (Howicks Group of Islands). We applied a tiered bioanalytical screening approach with a battery of six *in vitro* bioassays. Baseline toxicity was tested with the bioluminescence inhibition assay (Microtox). Specific modes of action, AhR-CAFLUX and BG1 were applied to screen dioxin-like and estrogenic activities. For the reactive mode of action we used AREc32 assay targeting the oxidative stress response in the adaptive stress response pathway, NfkB-bla assay as an indicator for immune response to infection and inflammation, and p53-bla assay as a response to DNA damage. First, we tested sediment samples from the three habitats to get insights into the bioavailability of the chemicals. Then we validated a QuEChERS extraction method on whole blood samples as a non-target approach for bioassays. We showed that there were no matrix interferences in any of the assays. Furthermore, 25-30 blood samples were analysed from each habitat to test if there are differences between them. Our results showed that sediments from the offshore site (Howicks) had consistently lower responses than the two coastal habitats. For turtle blood samples, three bioassays (Microtox, AREc32, AhR-CAFLUX) were positive, with the agricultural habitat (Upstart Bay) showing significantly higher responses compared to the other two sites. Overall, this study demonstrates that cell-based bioassays provide a suitable non-target analytical tool to evaluate combined mixture effects of organic chemicals in whole blood samples. Combining such tools with information on sea turtle population health status could present a powerful tool to evaluate associations with complex chemical exposure in nearshore environments.

TU187

Is the toxicity of pesticide mixtures occurring in agricultural influenced streams additive? An experimental approach with Daphnia magna

T.C. Schell, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; J. Zubrod, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; S. Lüderwald, Universität Koblenz-Landau / Institute for Environmental Sciences; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; W. Goedkoop, Swedish University of Agri Sciences / Department of Aquatic Sciences and Assessment

A broad variety of pesticides are used for crop production and may consequently be introduced during or following their application to adjacent agricultural streams. Ecological risk assessment is, however, based on single compounds. This procedure may not be protective if pesticides are present in complex mixtures due to potentially synergistic interactions. To empirically test for the protectiveness of current risk assessment approaches, we took advantage of the Swedish national monitoring program providing insights into the pesticides contamination pattern in agricultural streams. Based on these data, the acute and chronic toxicity of seven pesticide mixtures with the highest ecotoxicological potential was identified. To assess the acute toxicity of each pesticide mixture, *Daphnia magna* was exposed to the sum of toxic units ($\sum$TU), which was calculated based on the pesticides' reported individual acute toxicity, ranging from 0.0125 to 32. For the characterisation of the mixtures' chronic toxicity, daphnids were exposed to $\sum$TUs, based on the NOEC for reproduction, ranging from 0.25 to 8. It was uncovered, that a $\sum$TU of 2 to 10 is needed to cause a 50% reduction in mobility following an acute exposure. These data indicate that the pesticide mixtures show a lower toxicity than it would be expected from the pesticides' individual acute toxicity. Also during chronic exposures, a significant decrease in reproduction was observed at a ∑TU between 1 and 8, while higher ∑TU partly resulted in substantial mortality (up to 100%). The study's findings uncovered that mostly lower than additive or additive effects occur for pesticide mixtures, suggesting the concept of concentration additivity is often protective for pesticides in agricultural stream.

TU188

Does pathogen infection affect the elimination of toxic compounds?

K.E. Pedersen, B.L. Fredensborg, University of Copenhagen / Department of Plant and Environmental Sciences; N. Cedergreen, University of Copenhagen / Plant and Environmental Sciences

The importance of combined exposure to pesticides and pathogens to organism health has gained increasing recognition, mainly to improve methods for controlling pests in agricultural settings and for reducing mortality in beneficial insects. However, very few studies have quantified the interactions or described the mechanisms behind observed interactions between chemical stress and pathogen load. One suggested mechanism of interaction is *via* enzymatic processes e.g. the cytochrome P450 (CYP). CYP are initially involved in the detoxification of chemicals, and often up-regulated in response to chemical stress. On the other hand CYPs have been reported to inhibit or interfere with the innate immune response towards infections. The inverse relationship of CYP in detoxification and immune defense indicates a trade-off between these systems, a trade-off that can result in altered chemical elimination kinetics and delayed clearance of infection. The aims of this study were to investigate the effect of pathogen infection on the elimination kinetics of sublethal doses of a chemical using the flour beetle *Tenebrio molitor* as model organism. Propiconazole, a widely used azole fungicide, which has relatively low toxicity towards invertebrates, was chosen as chemical stressor, whereas the tapeworm, *Hymenolepis diminuta*, was chosen as pathogenic stressor. We hypothesized, that co-exposure to propiconazole and *H. diminuta* would result in 1) decreased CYP activity due to energy allocation towards immune defences and hence 2) decreased elimination rate of propiconazole. To investigate this, internal concentrations of radiolabeled propiconazole will be followed over time and CYP activity will be measured *in vitro* continuously before, during and after the chemical elimination phase in infected and non-infected beetles.

TU189

Spatial and temporal analysis of the risks posed by polycyclic aromatic hydrocarbon, polychlorinated biphenyl and metal contaminants in sediments in UK estuaries and coastal waters

E.E. Nicolaus, Cefas Lowestoft Laboratory / Environment and Ecosystems; R. Law, S. Wright, Cefas Lowestoft Laboratory; B.P. Lyons, Cefas Weymouth Laboratory

The environmental risks of 22 contaminants, comprising 6 metals, 10 PAHs and 6 PCB congeners occurring in UK estuaries and coastal waters were assessed as single substances. Sediment samples were taken within 12 nautical miles of the English and Welsh coastlines between 1999 and 2011. The measured environmental concentrations were compared to quality standards including ERL, ERM and EAC, all of which have been established internationally. Out of a total of 38,031 individual samples analysed, 42.6% and 7.7% exceeded the ERL/ EAC and ERM values, respectively. The highest Risk Characterisation Ratios (RCRs) for metals, PAHs and PCBs were observed for copper, fluorene and CB118 (2,3',4,4',5-pentachlorobiphenyl). In general, the highest concentrations of PAHs and PCBs were observed in 2011 in the Lower Medway indicating a potential risk to the aquatic environment. This study suggests that re-suspension of contaminants banned over 20 years ago is still an ongoing issue.

TU190

Lessons learned from testing PNECoral as reference value in a component based prediction of mixture effects of contaminants

E.S. Heimstad, NILU - Norwegian Institute for Air Research; D. Herzke, NILU - Norwegian Institute for Air Research / MILK

In the natural environment, living organisms are not only exposed to one single pollutant at a time, but to a variety of different contaminants. The exposure to a mixture of chemicals is first and foremost through food (prey), but also from water and the environment they live in. Component based-approaches are based on the concept that the effect of the mixture is a function of the effect of the individual compounds. The method of summing up PEC/PNEC or MEC/PNEC ratios, i.e. concentration addition, has been recommended as a justifiable mixture risk approximation in order to estimate in a first tier approach whether there is a potential risk for an exposed ecosystem (Backhaus and Faust 2012). Within the European regulation, the risk for wildlife and predators due to oral intake from lower trophic levels of bioaccumulative contaminants, is estimated with the use of PNECoral. PNECoral values represent dietary predicted no effect concentrations, below which food concentrations are not expected to pose a risk to birds or mammals (ECHA 2008). Results from long-term laboratory studies are strongly preferred, such as NOECs for mortality, reproduction or growth. If a chronic NOEC for both birds and mammals is available, the lower of the resulting PNECs may be used as the secondary poisoning assessment to represent all predatory organisms (ECHA, 2008). The method of summing up MEC/PNECoral ratios was used in order to evalute the potential risk for organisms in a study of urban terrestrial areas. In the study, the sum of MEC/PNECoral was calculated, where MEC was the median or 90 percentile concentration of contaminants measured in terrestrial organisms such as earthworm and bird eggs. PNECoral values were adopted from previously assessed and reported values. We will present the results from our calculations, and further evaluate and discuss the applicability of this component based approach; i.e. concentration addition for mixture risk prediction for our terrestrial urban study. References: Backhaus, T., Faust, M. (2012) Predictive environmental risk assessment of chemical mixtures: A conceptual framework. *Environ. Sci. Technol., 46*, 2564-2573. Human health risk due to polycyclic aromatic hydrocarbon (PAHs) exposure in Kumasi, Ghana; and excretion of PAH metabolites in cattle urine from urban and rural sites

N. Bortey-Sam, Hokkaido University / Environmental Veterinary Science; Y. Ikenaka, Hokkaido University / Graduate School of Veterinary Medicine; O. Akoto, Kwame Nkrumah University of Science & Technology / Chemistry; S.M. Nakayama, Hokkaido University / Graduate School of Veterinary Medicine; K. Asante, Council for Scientific and Industrial Research / ; C. Obirikorang, Kwame Nkrumah Uni. of Science & Technology / School of Medical Sciences; E. Baidoo, Kwame Nkrumah Uni. of Science & Technology / Chemistry; A. Saengtienchai, H. Mizukawa, Hokkaido University / Environmental Veterinary Sciences; M. Ishizuka, Hokkaido University / Graduate School of Veterinary Medicine

Previous studies of polycyclic aromatic hydrocarbons (PAHs) in particulate matter (PM10), soils and livers of wild rats indicated that the city centre of Kumasi, Ghana was severely polluted with high cancer potency, and fuel, wood/grass combustion were the dominant sources. Cattle urine were therefore collected from Kumasi (urban) and Offinso (rural), Ghana, to determine concentrations of 13 PAH metabolites (OH-PAHs), and investigate exposure levels of cattle to PAHs from the different sites. From the results, geometric mean concentrations (adjusted by specific gravity), GM_{SG}, showed that 2-OHNaphthalene (2-OHNap) was the most abundant OH-PAH and significantly higher in Kokote (rural) than the other sites. The GM_{SG} concentration (ng/mL) of $\sum_{9\text{-OH-PAHs}}$ decreased in the order, Kokote (44 ± 10) > Oforikrom (7.8 ± 7.4) > Saboa (6.9 ± 3.8) > Santasi (6.6 ± 2.7) > and T. Estate (5.2 ± 1.5). Principal component showed high association of 2-OHNap, 2-3-OHFle, 2-OHPhe and 3-OHPhe in Kokote indicating high exposure of cattle to PAHs in this area. Studies have indicated that exposure of rats and mice to naphthalene caused nasal and bronchiolar tumours, respectively. Based on the above studies and because urine could be used as a biomarker of exposure, effect and susceptibility, we collected human urine from 3 hospitals in Kumasi, and also from KNUST campus (where PAHs in PM10, soils and livers of wild rats were significantly low) to measure the concentrations of OH-PAHs and their association with oxidative stress. Results indicated that 2-OHNap (16 ± 28 ng/mL) was most abundant and highest in participants who visited Manhyia hospital (22 ± 40 ng/mL); and exposure could be through the use of naphthalene-containing-mothballs in water purification or insecticide. Highest level of 2-OHNap, (224 ng/mL), was found in urine of a female participant in Manhyia hospital, who reported symptoms of persistent cough, headache, dizziness, tachycardia, myalgia, nasal congestion and inflammation. 1-9, 4-OH-Phes, and 1-OHPyr were most abundant from a cyesis participant who visited Manhyia hospital. GM_{SG} (ng/mL) of $\sum_{9\text{-OH-PAHs}}$ from participants in the hospitals decreased in the order, Manhyia (26 ± 41) > Tafo (17 ± 28) > Atonsu (16 ± 21). Although levels of OH-PAHs in urine collected from KNUST were significantly lower than the hospitals, 2-OHNap was most abundant. Significant correlation between 2-OHNap in cattle and human urine could indicate a common source of naphthalene exposure.

TU192

Ecological risk of mixtures of radioactive and stable chemical compounds predicted by multi-substance species sensitivity distributions

L. Beaumelle, IRSN/PRP-ENV/SERIS/LRTE; C. Della Vedova, K. Beaugelin-Seiller, J. Garnier-Laplace, R. Gilbin, IRSN / PRPENVSERIS

Nuclear power plants release both radionuclides and stable chemicals to the environment under normal operating conditions, notably in river ecosystems. However, within the chemical regulatory framework, the ecological impact of those liquid releases is still evaluated based on the separate risks engendered by single substances. Until now, no attempt has considered radionuclides and stable chemicals in a holistic environmental impact assessment. This study contributes to improving existing regulatory instruments with the aim to propose an integrated risk assessment approach taking into account radioactive and stable chemical compounds altogether. Species sensitivity distributions (SSD) are widely used to estimate the potentially affected fraction of species (PAF) resulting from exposure to individual contaminant. This approach can be combined with mixture models in order to assess the multi-substance PAF (msPAF), a quantitative indicator of the ecological risk associated with mixtures. Such an integrated approach has rarely been applied to the case of mixtures that include radionuclides. Here, individual SSDs built for each radionuclide and stable chemical released to the Rhône River by 4 nuclear power plants were combined: the msPAFs associated with different release scenarios were derived using the concentration addition or response addition models according to the toxic mode of action of each substance. Due to the peculiarities of radionuclide ecotoxicology, the risk assessment is not straightforward and additional steps in the evaluation are needed. Particularly, chronic effect data are related to dose rates (energy deposited to the organisms by unit time due to ionising radiation from all radionuclides) and not directly to the radionuclide concentration in the exposure media. Those peculiarities also offer a unique opportunity to refine the 'traditional' approach (in which SSDs for each compound are derived before calculating msPAF using a mixture model) with a recently proposed approach in which mixture models are applied to each species separately before deriving a single multi-substance SSD. The latter approach is considered to be more robust, but has only been tested theoretically yet because it requires toxicity data for the same species for each compound, which is possible in the radionuclide case. The poster will compare the different approaches, and discuss their feasibility and realism regarding mixtures that include radioactive compounds.

TU193

Prospective risk assessment for mixtures of agricultural chemicals in surface water

C.M. Holmes, Waterborne Environmental, Inc.; M. Hamer, Syngenta / Environmental Safety; C. Brown, University of York / Environment Department; R.L. Jones, Bayer CropScience / Environmental Safety; L. Maltby, The University of Sheffield / Dpt of Animal Plant Sciences; E.M. Silberhorn, US Food & Drug Administration / Center for Veterinary Medicine; J. Teeter, Elanco Animal Health, a division of Eli Lilly & Co / Elanco Animal Health; M.S. Warne, DSITI / Water Quality and Investigations; L. Weltje, BASF SE / Crop Protection Ecotoxicology

In March of 2015, a SETAC Pellston workshop was held to help inform decision making around aquatic mixture risk assessments of chemicals using exposure scenarios and decision trees. The efforts were broadly grouped into three areas of chemical origination: agriculture, domestic, and urban influences (a separate integration group was charged with looking at overarching issues). The agricultural land use combined effect measures with exposure scenarios of chemical mixtures for field and catchment-scale using procedures that are recognized and used in regulatory schemes in the U.S., Europe and other parts of the world. Chemicals modeled were those used in crop protection and livestock production, and were considered to occur as mixtures (in time and space). Two types of scenarios were defined including a single unit that could represent a variety of typical chemical input locations (e.g., feed lot, agricultural field, pasture, aquaculture, biosolids applications, etc). The second scenario was multi-unit, combining several different uses within a single catchment/watershed. These assessments considered inputs from spray drift, surface runoff and erosion, and/or tile drainage systems on a daily basis over an extended period of time (e.g., from one to 30 years). Case studies included a single unit scenario modeled as a wheat field in Eastern UK, consisting of crop protection applications of 13 substances over the course of the year. This scenario used standard FOCUS soil, weather and receiving water body information for consistency. The case study of a multi-unit catchment scenario consisted of a combination of corn fields, pasture, and feedlot inputs based in part on the US EPA Iowa corn scenario used in pesticide registration evaluations. Manure from treated cattle containing two different pharmaceutical substances (a parasiticide and a macrolide antibiotic) was applied to corn fields as fertilizer, and also originated from pastured cattle. Twelve different active substances for crop protection were modeled on the corn field. These applications ranged from a pre-plant herbicide to a late-year fungicide application. A risk assessment decision tree looked at estimated environmental concentrations of all active substances on a daily basis, with subsequent mixture risks evaluated according to methodologies developed under a separate effects workgroup within the same Pellston workshop. A summary of the framework, methodologies and results will be presented.

TU194

Assessing the combined effects of chemical mixtures using novel alternative tools

S. Bopp, E. Berggren, European Commission - Joint Research Centre / Systems Toxicology Unit; A. Kienzler, European Commission - Joint Research Centre / DG Joint Research Centre IHCP EURL ECVAM; S. Van der Linden, European Commission - Joint Research Centre / Systems Toxicology Unit; A. Worth, Joint Research Centre / Institute for Health and Consumer Protection IHCP

Objective: Humans and wildlife can be exposed to an infinite number of different combinations of chemicals in mixtures via food, consumer products and the environment. It is practically unfeasible to test all these possible mixtures experimentally. Therefore smart strategies are needed to assess the potential hazards using new tools that rely less on *in vivo* testing and incorporate instead alternative experimental and computational tools. **Methods**: Recent literature has been reviewed and a survey on expert experiences in the assessment of combined effects been conducted. The current state of the art for the application of alternative tools was evaluated, focusing on the adverse outcome pathway (AOP) concept, *in vitro* methods, omics techniques, *in silico* approaches, toxicokinetic and dynamic energy budget (DEB) modelling, and on integrated approaches to testing and assessment (IATA). **Results**: Expert opinions in the survey regarding the use of novel tools in the risk assessment of mixtures were split between those applying them (often more in a research context) and those that generally think these tools are valuable but their use is currently limited because of lack of guidance, lack of data, or lack of expertise. The literature review showed how these tools allow deriving meaningful information on individual mixture components or whole mixtures, leading to a better understanding of the underlying mechanisms of their individual and combined effects. **Conclusion**: Using the above-mentioned tools in smart combination and an integrated way, different aspects regarding the hazard from combined exposure to multiple chemicals can be put into context. This will finally allow a better, mechanistically based prediction of mixture effects. In order to benefit from these tools in the hazard assessment of mixtures, more guidance on their use is needed to facilitate a more widespread application and integration into regulatory assessments.

Fate and Effects of Metals: Regulatory and Risk Assessment Perspective (P)

TU195

Establishing a shared methodology to develop reliable dose-response relationships for trivalent chromium

D.A. Vignati, CNRS / LIEC UMR; E. Battaglia, I. Aharchaou, LIEC Université de Lorraine CNRS; J.E. Groenenberg, LIEC Université de Lorraine /CNRS and Wageningen University

Risk assessment (RA) strongly depends on available ecotoxicological data and requires adequate quantification of hazard (exposure-response relationships) and exposure (i.e., concentrations likely to be encountered in the environment). In the case of chromium, RA must consider the simultaneous environmental occurrence of the two main redox forms, namely Cr(III) and Cr(VI), that have markedly different environmental behaviour and reactivity toward biological surfaces. Current consensus is that Cr(VI) is much more toxic than Cr(III), so that risk assessment and management have been particularly focused on this redox form. The concern over Cr(VI) is fully justified. However, Cr(III) ecotoxicity may be largely underestimated due to the lack of appropriate consideration of Cr chemistry in standardized (and not standardized) media used in hazard assessment and in the study of Cr(III) effects on the physiology and biochemistry of living organisms. The chemistry of Cr(III) in (standardized) test media is rarely considered in detail. The main issue is that soluble Cr(III) concentrations will be controlled by the possible formation of insoluble Cr(III) hydroxides in the test medium. This is of particular concern at circumneutral pH, but can occur also at slightly acidic pH depending on the added Cr(III) concentrations and medium composition. The formation of insoluble hydroxides lowers the actual solubility of added Cr(III) and may cause a marked decrease of the Cr concentration in the test solution over test time. When these factors are not examined, exposure-responses relationship established for Cr(III) in different studies will not necessarily provide adequate information on the actual exposure concentrations. The appropriate way to establish correct exposure-response relationship for Cr(III), especially under circumneutral conditions, is to use protocols originally developed for sparingly soluble substances. Appling the recommendations of such guidelines to Cr(III) requires repeated measurements of total and filterable concentration over the entire test duration, calculation of exposure concentration as time-weighed mean or geometric mean, expression of Cr(III) toxicity in terms of (modelled) free ionic species instead of total (filterable) concentrations, and provision of apparently trivial details such as aging of the spiked exposure medium that, as for the ecotoxicity of nanomaterials, can affect Cr(III) behaviour during ecotoxicological tests.

TU196

The classification of Attapulgitic clay under CLP/GHS

D. Heijerick, ARCHE; E. Drossos, G. Kacandes, Geohellas

GEOHELLAS mines and processes attapulgitic clay ("fullers earth") from near-surface, lateritic deposits in northern Greece. The material is produced in various particle sizes for use as absorbents in the food and feed industry. In edible oil applications, the material is able to remove oil contaminants, including dangerous 3-MCPD. In feed applications, the material absorbs mycotoxin, reducing the need for antibiotics in animal feed. While the present material has a long history of safe use, analyses indicate the existence of constituents that could trigger CLP classification. These are: cobalt (0,02%), chromium (0,3%), and nickel (0,3%) (three common laterite components), and crystalline silica (common in all types of clays). In order to determine the material's status under CLP/GHS rules, the material was examined mineralogically and chemically (weight-of-evidence approach), and subjected to MeClas tier analysis. Potential human health hazards related to the presence of Cr and crystalline silica were ruled out using mineralogical data on respirable silica content (SWERF method) and on the valence state of Cr in the minerals present. The mineralogical data further demonstrate that Ni exists as an isomorphic substitution in the clay structure, ruling out the Carc.Cat.1 classification associated with other forms of Ni. To address potential environmental hazards, a speciation-based assessment was first done assuming that 100% of the metals are bioavailable (MeClas Tier-1). The result was an Aq. Chronic 3 classification due the combined effect of Co, Cr, and Ni. Because 100% bioavailability is not possible with the natural clay, a refinement was conducted using data from a 24h T/Dp test (pH6, 100 mg/L) on the finest fraction of the attapulgitic clay. These data indicate low release factors of < 0,1% for Co and Cr, and < 1% for Ni (percent of total metal concentrations), and allow for the release factors to be transformed into 28d-release rates (linear extrapolation; worst-case assumption). The extrapolated data give values of 2.53%, 0.59% and 23.16%, respectively. Inclusion of these release rates in the calculations (MeClas Tier-2) removed the provisional Aq.Chronic 3 classification. Based on evaluation of the hazard endpoints, it was concluded that the attapulgitic clay in all its forms should not be classified for any human health or environmental hazard under CLP or GHS.

TU197

Water Framework Directive - Overview of Water Quality Standards and initial assessment for molybdenum

D. Heijerick, ARCHE; N. Van Roey, SADACI; S. Carey, IMOA

Environmental Quality Standards (EQSs) are tools used for assessing the chemical status of waterbodies. In summary, the maximum acceptable concentration and/or annual average concentration are established for priority substances. When these threshold concentrations are met in a waterbody, the chemical status of the waterbody can be described as 'good'. EQSs should protect freshwater and marine ecosystems from possible adverse effects of chemicals as well as human health via drinking water or ingestion of food originating from aquatic environments. Several different types of receptor therefore need to be considered, i.e. the pelagic and benthic communities in freshwater, brackish or saltwater ecosystems, the top predators of these ecosystems and human health. Five relevant EQS were considered for the evaluation of molybdenum: quality standard for the protection of the water column ($QS_{water,eco}$), protection of sediment organisms ($QS_{sediment}$), protection of predators (mammals, birds) from secondary poisoning ($QS_{biota,secpois}$), protection of men from secondary poisoning due to the consumption of contaminated fishery products ($QS_{biota,hh\ food}$), and protection of men from poisoning due to consumption of contaminated drinking water (QS_{dw}). The final $QS_{water,eco}$ for molybdenum in the freshwater and marine environment were 12.7 mg Mo/L and 2.28 mg Mo/L, respectively, and reflect the PNEC-values that were included in the REACH registration dossier for Mo-compounds. No formal drinking water guideline value has been adopted, but a health-based value has been put forward by WHO (2011) and is used as a starting point for the calculated $QS_{dw,hh}$ of 82 μg Mo/L, taking into account a removal efficiency of 15 %. With regard to the $QS_{biota,hh}$ for molybdenum, a value of 207 mg/kg was derived. This $QS_{biota,hh}$ must then be translated to a concentration in the water column according to the formula "$QS_{biota,hh,water} = QS_{biota,hh}$ / BAF". As the BAF for essential elements depends on the exposure concentration, there is no straightforward option for solving this equation. However, bioaccumulation data for the most sensitive organism in the aquatic environment (Regoli et al, 2012) demonstrated that molybdenum was properly regulated in aquatic organisms when exposed to concentration levels that equal the $SQ_{eco,water}$., with internal concentrations well below the critical threshold of 207 mg/kg. Therefore it was not required to derive a $QS_{biota,secpois}$ and/or $QS_{biota,hh}$.

TU198

Application of descriptive and multivariate analysis for obtaining the pollution markers of untreated wastewater in Novi Sad, Serbia

S. Pap, University of Novi Sad Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; M. Vojinovic MIloradov, Faculty of Technical Sciences University of Novi Sad / Department of Environmental Engineering and Occupational Safety and Health; M. Brboric, V. Bezanovic, D. Milovanovic, D. Ubavin, University of Novi Sad, Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; I. Mihajlovic, Faculty of Technical Sciences University of Novi Sad; M. Djogo, University of Novi Sad Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health

Untreated mixed effluents (a mixture of municipal and industrial wastewater and surface runoff) are a complex, multivariate environmental systems, in which a number of physical, chemical and biological processes occur simultaneously. For the selection of an appropriate treatment process and the design of the stable conditions for optimum performance of the wastewater treatment plants (WWTPs), it's necessary to have a detailed information about the sources, composition and levels of pollutants in the wastewater. This study examined the relationship between these processes through analyzed parameters of untreated wastewater in Novi Sad, Serbia. The samples of wastewater were taken from one of the most burdened discharges in the city of Novi Sad during 2012-2014. Experimental data were analyzed by basic statistical methods for determination of mean and median values, standard deviations, minimal and maximal value of the measured parameters. Then association of cluster analysis (CA) with the principal component analysis/factor analysis (PCA/FA) was applied in order to establish a model link between parameters and sampling seasons, as well as to detect and diagnose abnormal events during monitoring periods, which helps in the design of the wastewater treatment plant in the future. Hierarchical CA grouped the eleven monitored periods into three clusters based on their similarities, corresponding to seasons of low polluted period (LP-P), moderate polluted period (MP-P) and high polluted period (HP-P). For the three different groups using PCA/FA three factor model was constructed and resulted in 70.08%, 67.54% and 76.99% of the total variance in the wastewater quality datasets of LP-P, MP-P and HP-P, respectively. PCA/FA indicates that in each period beside organic pollution primarily heavy metals are responsible for wastewater quality variation (point source: industry). These heavy metal factors are interpreted as metal pollution from the industrial effluents. Each factor has strong positive and negative loadings on Pb, TCr, Zn, Cd and Fe concentrations. Large data base obtained within this study could give relevant information about the physico-chemical status of wastewater in order to establish the best treatment technology of wastewater at selected wastewater discharge. **Acknowledgement:** This study has been financially supported by Ministry of Education, Science and Technological Development, Republic of Serbia (III46009 and TR34014).

TU199

Antimony fate modelling approach for regional nuclear risk assessment

T. GIL DIAZ, J. Schäfer, F. Pougnet, Université de Bordeaux; M. Abdou, UMR5805 EPOC / Geochemistry; L. Dutruch, Université de Bordeaux; F. Eyrolle-Boyer, IRSN Cadarache; A. Coynel, Université de Bordeaux

Antimony (Sb) is a highly toxic ubiquitous oxyanion that has poorly been studied in the environment until recently. However, there is no global view of its biogeochemical cycle and the processes taking place (behaviour, transformation and transport), especially in aquatic systems. In addition, it is a refractory fission product in nuclear power plants (NPP), released and detected after the Chernobyl (ChNPP, Ukraine 26th April 1986) and Fukushima Dai-ichi (FDNPP, Japan 11th March 2011) accidents both in soils and marine invertebrates at unpredictable sites and time lapses. The aim of this work is to determine the environmental fate and potential dispersion of radioisotopes before accidental NPP events in the Gironde Estuary (France), the largest estuary in southwest Europe subjected to two NPPs (*i.e.*, upstream and within the salinity gradient area). Measurements on stable Sb show a non-conservative behaviour along the salinity gradient with enhanced addition processes taking place during low freshwater discharges. Dissolved concentrations (Sb_d) range from ~0.12 μg l^{-1} at S=0 to ~0.4 μg l^{-1} at S>27, higher than available measurements from the Atlantic coast off Nantes (0.21 ± 0.01 μg l^{-1}). Estimated net fluxes (Boyle's method) range from ~20 to ~420 kg day^{-1}, compared to average gross fluxes of ~2.5 and ~14 kg day^{-1} registered from 2004-2014 at the estuary upstream limit (*i.e.*, La Réole). Variations in particulate concentrations (Sb_p) during different discharges along the estuary are less evident. Distribution coefficients indicate that high suspended particulate matter (SPM) favours Sb_p up to ~90% of the total Sb with SPM ~1000 mg l^{-1} (corresponding to the maximum turbidity zone, MTZ). Estimations on radionuclide generation after an accident indicate critical times for radiotoxicity exposure (*i.e.*, γ and β^- radiation) within the first 4 days (tidal scale) and 1 month after the accident, with environmental persistence of several years for the latter case (seasonal implications for the ^{125}Sb isotope: half-life of 2.76 y). This study shows that freshwater discharge and the resulting position and dynamics of the MTZ will play a major role in transport and residence times of Sb radionuclides towards the coast and within the Gironde Estuary, including the risk of upstream transport of radioactive particles to Bordeaux during summer draught.

TU200

Application of improved scientific approaches in support of metal risk assessments

K. Oorts, ARCHE; I. Schoeters, Rio Tinto

Several aspects must be accounted for in order to perform a scientifically-sound risk assessment of metals in soil, such as e.g. essentiality and variability of soil properties influencing the bioavailability and toxicity of metals. During the last 2 decades, a lot of research has been performed in these fields and numerous chronic metal toxicity data were generated for various terrestrial species and microbial functions in different soil types. From these data sets, models were developed for correction for differences in bioavailability among soils or between laboratory and field conditions. For many metals, the large amount of chronic toxicity data for different species and functions allow the application of the species sensitivity distribution approach (SSD) to derive soil quality standards. This work was mainly triggered by the European legislation on chemical management (REACH and the former Existing Substances Regulation) and the data were therefore primarily used to derive predicted no effect concentrations (PNEC) for prospective risk assessment. The data can however also be used for other purposes. For example, different combinations of effect level (EC_x) and protection level (hazardous concentration within the SSD, HC_p) can be considered for the derivation of soil quality standards. The use of the SSD approach also allows predicting the potentially affected fraction (PAF) of terrestrial organisms for a specific metal concentration in a specific soil. In order to facilitate the setting of ecological quality standards for metals in soil for different protection purposes (e.g. prospective risk assessment or remediation) and in different jurisdictions, while still making maximal use of the wealth of data and models already available, a tool is being developed that allows using the data and models originally developed for the European prospective risk assessments towards a more flexible derivation of soil toxicity thresholds. This can be done by allowing selection of the different effects level (e.g. EC_{10}, EC_{20}, EC_{30} or EC_{50}) as a basis for the assessment, the protection level required, the group of organisms to be protected, bioavailability models to be included etc. The advantages of this approach are harmonization of toxicity datasets and bioavailability corrections used and the enhanced transparency in the derivation of ecological quality standards for metals in soil for different goals and different scenarios.

TU201

Implementation of soil bioavailability concepts in the determination of German precautionary values

J. Roembke, ECT Oekotoxikologie GmbH; E. Fries, Federal Institute for Geosciences and Natural Resources (BGR); E. Giese, Federal Environment Agency; S. Jaensch, ECT Oekotoxikologie GmbH; D. Rückamp, C. Stange, Federal Institute for Geosciences and Natural Resources; J. Utermann, Federal Environment Agency; K. Oorts, ARCHE

According to the German Federal Soil Protection Act (1998), soil precautionary values are defined as “soil values which, if exceeded, shall normally mean there is reason that concern for a harmful soil change exists, taking geogenic or wide-spread, settlement-related pollutant concentrations into account”. In the German Soil Protection Ordinance (1999), such values are given for seven metals. Recently, more values have been proposed for arsenic and thallium. All of them were defined based on total concentrations (“aqua regia”). Regarding the pathway “soil – soil organisms” it is well known that there is a poor correlation between total metal concentrations and their effects on microbes, plants and invertebrates. There is also a general agreement that a realistic risk assessment of metals should be preferentially based on concentrations of their biologically available fraction – but it is not clear which fraction should be used for regulatory purposes and how to measure it. In any case the implementation of bioavailability should account for several aspects affecting metal toxicity to soil organisms, such as the differences between laboratory and field conditions (including ageing processes) or the variations in the properties of natural soils (i.e. pH, clay content, CEC etc.) – not to mention the form of the metal (i.e. water-soluble salts vs. metal oxides etc.). Corrections for ageing and varying soil properties have recently been used in the prospective risk assesment of metals in the European Union (e.g. in REACH dossiers). Referring to these experiences the German Federal Environmetal Agency has launched a project in order to develop a transparent concept to derive soil precautionary values considering ecotoxicological effects of bioavailable fractions of metals.. The work is divided in four steps, starting with a literature review on existing concepts on the derivation of soil values for metals. Based on the results of this compilation, a specific testing and assessment concept will be formulated as a basis for the third step, i.e. practical testing. The latter will focus on a limited number of metals, soils, ecotoxicological test methods and extraction methods. The concept will be tested for a cationic metal (copper) and an oxyanion (either arsenic or molybdenum). In the final (fourth) step all available information will be used to propose a new concept for including bioavailability into the derivation of future precautionary values.

TU202

Bioaccessibility and Health Risk Assessment of Potentially Toxic Elements in urban soils of Lagos, Nigeria

A. Famuyiwa, pure and applied chemistry; C. Davidson, University of Strathclyde / pure and applied chemistry

Total or pseudo-total extraction over estimates the risk of human exposure to PTE since only a fraction is bioavailable or bioaccessible. Bioaccessibility extraction tests simulate the human gastro-intestinal tract especially of children, the target group most susceptible to accidental or deliberate ingestion of non-food substances. The protocol estimates the actual fraction that is soluble and available for absorption into the blood stream. In this work, Lagos urban soils were tested for bioaccessible PTE’s and potential risk assessment. A total of 20 soil samples were studied, comprising soils collected from public access areas and from known point sources of PTE such as dumpsites and industrial areas. Pseudototal PTE concentrations were determined by digesting 1 g of soil in 20 ml *aqua regia* using a microwave digestion system (Mars Xpress, CEM, UK). The Simplified bioacccessibility extraction test (SBET) using pH adjusted (1.5) glycine was employed. Extracts were analysed for PTE by inductively coupled plasma mass spectrometry (ICP-MS Model 7700, Agilent Technologies, UK). Copper, Pb and Zn generally showed higher bioaccessibilty (% BA with respect to pseudototal concentrations) than Cr, Fe, Mn and Ni which may reflect an anthropogenic, as opposed to geogenic origin. Risk assessment was estimated by calculating the amount of soil that a hypothetical child needs to ingest to reach a toxicologically significant level. The data were compared with tolerable daily intake (TDI) values calculated for a child weighing 10 kg using the human-toxicity maximum permissible levels published by Baars et al (2001)[1] The obtained data and corresponding daily intakes calculated indicated that all soils were able to pose risk of Pb toxicity in the event of accidental soil ingestion of 10 g/day. Only three out of all the soils exceeded TDI for Pb in the case of conservative consumption of 100 mg/day. More worrisome was one of the dumpsite soil samples in which only about 80 mg of soil needed to be ingested to deliver the TDI for a 10 kg child. The TDI for Zn was exceeded in almost half of the soils studied assuming soil pica tendencies (10 g/day). Generally, for all PTE studied, Pb appeared to be the PTE of greatest concern considering both typical and excessive soil intake by a child. 1. Baars A.J, Janssen P.J.C.M,Hesse J.M,Van Apeldoorn M.E ,Meijerink M.C.M,Verdam L, Zeilmaker,M.J, *Re-evaluation of human-toxicological maximum permissible risk levels*. Netherlands, 2001.

TU203

Introducing speciation changes, human bioaccessibility and bioavailability in the risk evaluation of dietary inorganic arsenic intake: a Belgian case study

N. Waegeneers, A. Ruttens, CODA-CERVA / Trace Element Service; T. Sergent, UCLouvain / Institut des Sciences de la Vie; G. Du Laing, Ghent University / Laboratory of Applied and Analytical Ecochemistry; Y. Schneider, UCLouvain / Institut des Sciences de la Vie; T. Van de Wiele, Ghent University / Laboratory Microbial Ecology and Technology

Arsenic (As) is an ubiquitous element frequently present in food items. Human health risks related to its dietary intake are not linked to total As intake, but depend on the chemical form (speciation) in which As is taken up. Hence normative legislation should preferably be speciation-based in the case of As. To assess the risks associated to dietary As intake, the knowledge of the internal exposure to different As-species is necessary, and this can only be determined if speciation changes during food preparation and food digestion are known. The BIOTRAs project aimed at incorporating these changes and knowledge about As-species bioaccessibility and bioavailability into the risk assessment of dietary As intake in Belgium. Different food items were analysed before and after preparation to determine the effect of preparation on As concentrations and speciation. The prepared food samples were subjected to a sequential in vitro digestion system (Unified Barge Method). To mimic colon digestion, the intestinal digests were incubated with colon suspension sampled from the SHIME reactor. The bioaccessible fraction was collected by centrifuging the small intestine- or colon digests. Apparent permeability values of As and its species from the digested food matrices were obtained by means of the Caco-2 cell system. From these data, human intestinal absorption values were derived (bioavailability). To perform As in- and uptake calculations, different food consumption scenario’s were elaborated based on the Belgian Food consumption survey and literature data. To evaluate the risk of inorganic As (iAs) in- and uptake, margins-of-exposure were calculated. An increasing consumption of typical iAs sources (e.g. rice, hijiki seaweed) increases the intake of iAs, although cooking these food items in an excess water mitigates the increase. The calculated systemic uptake of iAs for a usual Belgian consumption pattern is calculated as 7 μg/d. A high consumption of selected food items leads maximally to a doubling of the iAs intake. Ethnic groups with a rice-based diet have a 25- to 100-times higher uptake of iAs than the average Belgian population, depending on the consumed amount of rice and its preparation method. No health risks due to iAs intake or uptake are expected for the general Belgian population. A long-term ethnical rice-based diet is discouraged for people with an increased risk for lung cancer such as smokers.

TU204

Phytomanagement of eutrophic wetlands polluted by mine wastes: the role of the biogeochemical processes

J. Álvarez-Rogel, M. Tercero Gómez, H. Conesa Alcaraz, Escuela Técnica Superior de Ingeniería Agronómica. Universidad Politécnica de Cartagena / Ciencia y Tecnología Agraria; I.M. Párraga, Universidad Politecnica de Cartagena / Departamento de Ciencia y Tecnología Agraria; M. González-Alcaraz, Faculty of Earth and Life Sciences, VU University / Ecological Science

In the studies presented in this work we evaluated the effectiveness of combining liming and vegetation for the phytomanagement of saline eutrophic wetlands polluted by mine wastes. We assayed the effect of lime application and growth of the halophyte Sarcocornia fruticosa (L.) A.J. Scott on metal dynamics in pots and soil columns under variable hydric conditions. Polluted soils from the La Marina del Carmolí salt marsh with a pH~6.4 and polluted soils from Lo Poyo salt marsh with pH~3.1. Both soils showed high EC, up to 20 dSm^{-1}, calcium carbonate contents below 6 g kg−1 and low concentrations of TOC and TN. In both soils, the total heavy metal concentrations were high, especially for Al (13-16 g kg^{-1}), Fe (61-118 g kg^{-1}), Pb (5-7 g kg^{-1}) and Zn (4-500 g kg^{-1}). A lime amendment with a pH=8.9 in a 1:2.5 water suspension, derived from the marble industry, was added to each soil at a dosage of 2%, giving four treatments: neutral soil from La Marina del Carmolí with and without liming and acidic soil from the Lo Poyo salt marsh with and without liming. Pots (13.5cm×14cm) and columns (15cm x 60cm) were filled with the treatments. The experiment was performed in two phases. Phase 1: cuttings of S. fruticosa were planted in the pots, which were irrigated for 10 months with eutrophic water and soluble metal concentrations (Al, Cd, Mn, Pb, and Zn) and plant survival, plant biomass, and plant metal content were determined. Pots without plants were irrigated in the same way. Phase 2: the contents of six pots per soil treatment (three with S. fruticosa and three without plants) were transferred to the corresponding columns. Each column was placed inside a larger container filled with synthetic eutrophic water enriched in nitrogen and organic carbon. The water level (WL) in the containers was maintained at 20 cm below the soil surface for five weeks (1st High WL) and then at 45 cm during the following five weeks (1st Low WL), repeating this cycle once more along the study (2nd High WL, 2nd Low WL.The pH, Eh, and soluble metal concentrations (Cd, Cu, Fe, Mn, Pb, and Zn) were measured regularly at each depth for 18 weeks. The results of both experiments showen that choice of the most appropriate phytomanagement techniques for recovering eutrophic wetlands polluted by metal mine wastes depends on the particular characteristics of the soil-water-plant system, the hydric/flooding regime, and the type of pollutant (nitrogen, phosphorus, and metals).

TU205
Impact analysis in the frame of Life Cycle Assessment, of the toxic metals emitted by industrial activities to agricultural soil in Fez area
M. Ghazi, Teriva Environment; A. Kouchou, Fes University; J. Duplay, Strasbourg University; J. Thoisy-Dur, INRA / UMR ECOSYS France Plateforme BiochemEnv INRA UMR ECOSYS Versailles cedex France; N. Rais, N. EL Ghachtouli, Fes University; F. Elsass, INRA / UMR ECOSYS France Plateforme BiochemEnv INRA UMR ECOSYS Versailles cedex France
Contamination by trace metals in agricultural soils in the Fez region are linked to their irrigation using water from the Oued Fez. The latter is fed by sewage from surrounding industries and the city, which have a high pollution load in spite of treatment and risk minimization's efforts. Several reports and studies in this region confirmed the state of high metallic pollution in Oued Fez's waters and its confluence with the Oued Sebou. The effluents of the tannery and textile industries as well as those of the metal finishing industry, present the greatest risk because of the use of some metals in their processes. This work aims at interpreting the metals quantities which are emitted during the industrial activities life cycle, in terms of potential impacts on water, soil and human health. The life Cycle Assessment (LCA) was adopted as multi-criteria methodology for identifying and quantifying the major contributions related to various local industries' metal emissions. In particular, it is question of analyzing the aquatic and terrestrial ecotoxicity, and human toxicity. The characterization of these impacts takes into account the fate of trace metals emissions from their sources to the waters, sediments and agricultural soils through irrigation water. Their toxic effects on aquatic species and human health are also considered. The fate of metals emissions was determined by a geochemical study in the areas at different sites. The analysis of total concentrations and bioavailable fractions was conducted on the industrial effluents and the three environmental compartments: water, sediments and soils. The effect factor is based on the effect concentrations HC_{50} of the Impact2002$^+$ database and by specifying some parameters such as the partition coefficient of trace elements, the density and the moisture content of the soil. At this stage of analysis, it could be identified that the trace elements Cr, Ni, Cu and Zn are the major contributors to the terrestrial ecotoxicity. This is due to several causes combined or separated: high total concentrations in the soil, a greater mobility of bioavailable fractions and/or lower concentrations of toxic effect.

Higher tier tests in the risk assessment of plant protection products (P)

TU206
Reflections on bird and mammal risk assessment: past, present and future
A.C. Brooks, Cambridge Environmental Assessments / Regulatory Ecotoxicology; M. Fryer, Chemicals Regulation Directorate / Ecotoxicology; A. Lawrence, Cambridge Environmental Assessments / Regulatory Ecotoxicology; S. Taylor, Cambridge Environmental Assessments; J. Pascual, BASF SE / Ecotoxicology
The use of plant protection products on agricultural crops can result in exposure of birds and mammals to toxic chemicals. The risks from such exposures are assessed under the current guidance document, EFSA (2009). The risk assessment procedure is sequential, moving from worst-case screening steps through to increasingly more realistic, higher tier risk assessments. The current guidance document was designed to increase the realism of these theoretical risk assessments, in comparison to its predecessor (SANCO/4145/2000). Since its adoption over 5 years ago, many plant protection products have been registered successfully using EFSA (2009). However, there are still many cases where low risks cannot be demonstrated using the current scheme, even using extensive and robust higher tier refinements. The aim of this presentation is to discuss the implementation of the current scheme, including levels of conservatism in input parameters, and interpretation by regulatory authorities, together with proposals for how the guidance document could be improved when it is revised in the not too distant future. The content of this presentation forms the basis of an invited manuscript to be published as a 'Focus' article in Environmental Toxicology and Chemistry.

TU207
Honeybee brood studies under field conditions: is there a difference of the brood termination rate compared to semi-field studies?
J. Lueckmann, Rifcon GmbH; R. Becker, BASF Aktiengesellschaft
Based on EU Regulation 1107/2009/EC the current regulatory risk assessment on bees has to address the risk to honeybee larvae or honeybee brood. According to the new "EFSA Guidance Document on the risk assessment of plant protection products on bees (*Apis mellifera*, *Bombus* spp. and solitary bees)" (EFSA 2014), both, the Oomen bee brood feeding test (Oomen *et al*. 1992, EPPO Bulletin 22: 613–616) as well as the OECD Guidance Document 75 (2007) are given as the two higher tier options to refine the risk on honeybee brood if concerns are raised in tier 1. The evaluation of historical data from semi-field studies according to OECD GD 75 showed a strong variability of the brood termination rates (BTRs) as the key endpoint (Becker *et. al* 2015, Julius-Kühn-Archiv 450: 83-92). Therefore the performance of EPPO 170 field studies using the OECD GD 75 bee brood evaluation might be one option to get more reliable BTR data, which was envisaged already some years ago in 2009 (Becker *et. al* 2009, Julius-Kühn-Archiv 423: 43-44), used for several years, and followed-up by Giffard & Huart (2015, Julius-Kühn-Archiv 450: 111-120). However, broader data sets supporting the benefit of this combined methodology are still lacking. Thus, the current presentation summarises control BTRs gained under field conditions which have been performed since 2012 in Germany. They were conducted according to EPPO guideline 170 (4) (2010) with detailed brood evaluations according to OECD GD 75 and covered the assessment of one or two brood cycles during and after the exposure of the bees to flowering crops. In addition, studies covering the analysis of a 2nd brood cycle with free flying honeybee colonies subsequent to a 1st brood cycle derived from semi-field trials were also considered. Overall the evaluation covers the data of almost 50 control colonies. These data were compared to the updated findings on control BTRs from almost 70 semi-field bee brood studies (Becker *et. al* 2015, Julius-Kühn-Archiv 450: 83-92) now. Finally, the advantages and disadvantages of both test approaches are discussed.

TU208
Semi-field Study for the Honey Bee (Apis mellifera) using a Micro-Colony System
C. Jenkins, Envigo / Terrestrial Ecotoxicology; K. Barrett, Envigo / Envigo Consulting Limited; J. Gray, Envigo / Terrestrial Ecotoxicology
Higher tier studies, which require the use of bee colonies and more complex test designs, are often difficult to evaluate because high levels of background mortality are seen in controls and yet the findings from these multi-disciplinary studies are used to assess the potential for risk to bee populations exposed to plant protection products. Currently, tests are frequently based the 2007 OECD Series on Testing and Assessment: Number 75 "Guidance document on the honey bee brood test under semi-field conditions," with an initial 7 day direct exposure in a tunnel after the application of the test article, followed by a 19 day observation period outside of the tunnel. This only addresses the impact on eggs present at the time of application and not the later stages of development, which some test articles are known to have an impact on. Therefore, there is a need to develop a test that is sufficiently robust to provide reliable and reproducible data within a contained environment to allow the bee colonies to survive for a period of at least 22 days (time taken for development of a newly laid egg to emergence) so that all stages of development can be assessed. This study is designed to evaluate the survival of un-treated adult bees and associated brood under test conditions to verify that control colonies exhibit adequately low mortality rates in the absence of test article to justify the use of mini-colonies of ca. 2000 adults. In addition, both conventional frames and specially divided frames, which allow the queen access to specific areas for egg laying are being evaluated. The hives are provided with adequate food stores above a queen excluder to prevent her from using the food frames for egg-laying. This is in contrast to the conventional approach of providing the minimum amounts of stores to prevent their use in preference to incoming nectar and pollen which may (in a real study situation) contain the test substance, although bees in fact only use the stores when there is no incoming food. Individual hives are manipulated to ensure that all stages from eggs to old larvae are present at Time 0 (day of application). Timed assessments of all life stages allow comparison of the previously used Oomen method with the current OECD 75 and also the traditional frames with the new divided frames. The selected hives are established in the enclosures (*ca.* 70 $m^{2)}$ of flowering *Phacelia* with the mortality of foragers being monitored during the pre-assessment period.

TU209
Minimum Detectable Differences as a criterion to assess the reliability of micro- and mesocosm studies
U. Hommen, Fraunhofer IME; L. Dören, R D; I. Roessink, Alterra / ERA team; T. Strauss, Research Institute gaiac / Research Institute Gaiac; S. Taylor, Cambridge Environmental Assessments
The new European guidance document on tiered risk assessment for plant protection products for aquatic organisms in edge-of-field surface waters requires reporting the minimum detectable differences for tests on significant differences between population abundances in the controls and treatments in mesocosm studies in order to assess the reliability of the statistical analysis. If the study should be used to derive a regulatory acceptable concentration under the ecological threshold option, a reliable analysis of direct effects should be possible for a least 8 potentially sensitive populations. However, no clear guidance is given

on how to assess if the MDDs are sufficiently robust. Recently, Brock et al. (2015) proposed how the MDD could be calculated and suggested also a criterion on how many sampling dates the MDD should be below specific values to allow a reliable analysis of direct effects on a taxon. Here we will present experience with the MDD concept in the re-evaluation of older mesocosm studies and the use of MDDs in studies recently conducted. We will focus on how many and which potentially sensitive taxa fulfilled the criterion proposed by Brock et al. (2015) and how this relates to different test systems, level of taxonomic identification, sampling methods, sampling frequency and mode of action of the test item. We will discuss the practicability and relevance of the MDD criterion for different taxa and the potential consequences for the role of mesocosm studies in the aquatic risk assessment in the future.

TU210

Tiered testing for sediment organisms: towards calibration of the EFSA proposal

P. Lopez-Mancisidor, Dow Agro Sciences LLC / Ecotoxicology; G. Meregalli, Dow AgroSciences Italia srl / Environmental Regulatory Sciences Ecotoxicology; I. Barber, J. Wheeler, Dow Agrosciences

The EFSA Scientific Opinion (SO) on the effect assessment for pesticides on sediment organisms in edge-of-field surface water proposed a tiered effect assessment approach for sediment organisms. The aim of this study was to assess whether the tiered approach is suitable for sediment organisms. The global data requirements for sediment testing were reviewed and, example molecules covering different modes of action (insecticide, fungicide and herbicide) were selected. Datasets were compiled for each EFSA tier; i.e. laboratory, modified laboratory studies and species sensitivity distributions as well as full mesocosm studies. All data were extracted from the regulatory (EFSA conclusions, DARs, RARs and US-EPA documents) and the open literature. Based on the laboratory data Regulatory Acceptable Concentrations (RACs) in sediment are were determined. From the higher tier data, information concerning sediment-associated organisms (typically emergent insects and rooted macrophytes) is was extracted. A comparative analysis of these data is will be presented to validate/calibrate the assessment factor used to trigger additional testing (tiers 2 and 3) or conclude on acceptable risk.

TU211

Do stable isotope signatures and elemental stoichiometry mirror toxicant-induced changes in predation success?

J. Zubrod, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; D. Englert, B. Fuß, S.R. Lüderwald, R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment

Contaminant-induced changes in food-web structures are difficult to detect using traditional methods employed in multi-species studies. Stable isotope signatures and elemental stoichiometry may help to overcome this problem as both can provide information about the food source utilization by consumers. To assess the suitability of these tools, we conducted an experiment with the omnivore amphipod *Gammarus fossarum*, who had the choice to feed on black alder leaves or to prey on mayfly nymphs (*Baetis* sp.). As a model stressor, we applied thiacloprid at 0.75 μg/L, which is known to increase the predation success of *Gammarus* on *Baetis*. To assess all factors potentially affecting gammarids' stable isotope signals and elemental composition, a factorial approach was employed (insecticide x *Baetis* x leaves). The consumption of *Baetis* and leaves was recorded over two weeks in microcosms (*n*=5-10) and stable isotope signals and elemental stoichiometry, for N and C, were finally analyzed in gammarids and both food sources (*n*=5). As expected, thiacloprid exposure increased the predation success of *Gammarus*. This pattern was, however, not reflected by elemental stoichiometry, neither using C, N, nor the C:N ratio. Moreover, N content differed significantly between unexposed and exposed gammarids fed only *Baetis*. As these treatments did not differ regarding predation success, this observation indicates a differential N assimilation in response to insecticide exposure, which would rule out elemental stoichiometry as a tool to trace food source utilization under chemical stress. In contrast, stable isotope signatures mirrored the increased predation success of gammarids on mayfly nymphs, while no significant difference in signatures was detected between unexposed and exposed gammarids when receiving the same single food source. Furthermore, while calculations on a mass basis revealed an increase of the proportion of *Baetis* in the diet of *Gammarus* from 15% to 20%, the isotope data showed an increase in the proportion of assimilated food from 13% to 28%, indicating a stronger effect of the insecticide on food assimilation than on food uptake. Although further experimentation is required to draw final conclusions, the present study thus indicates stable isotopes as a promising tool to mirror contaminant-induced changes in food-web structures that additionally provides information about the physiological usage of food sources being not obtainable using traditional methods.

TU212

Can we combine data from avian reproduction studies with different test species to improve risk assessments?

A. Lawrence, Cambridge Environmental Assessments / Regulatory Ecotoxicology; S. Taylor, Cambridge Environmental Assessments

When conducting risk assessments for birds and mammals potentially exposed to plant protection products, there may be more than one study available for each endpoint (acute, reproduction). The current guidance document for birds and mammals (EFSA, 2009) states that it is possible to combine acute data on different species using a geometric mean approach, and that the intended level of protection is preserved. The guidance states that for reproductive studies, the geometric mean approach is currently not supported. When more than one reproduction study is available on the same species, the guidance states that it may be possible to combine or merge the studies as if they were one study. In order to do this, various criteria must be met, including: studies conducted to a similar protocol or guideline, same key endpoints assessed, similar dose responses present in each study, same test species used, same protocol used, similar number of animals used, same endpoints measured and same test conditions used. When two avian reproduction studies are available, many of the above criteria are fulfilled, because the protocols are the same. Studies may be available for different test species, however, typically mallard duck and bobwhite quail. This poster will describe how it may be considered acceptable to combine the reproductive toxicity data for two avian test species when the endpoints are derived from very similar studies, to improve accuracy of endpoints used in risk assessment. This may be especially relevant when EC10 values cannot be reliably calculated, and dose spacing is wide, leading to large differences between NOEL and LOEL.

TU214

MDDs in micro-arthropod field testing

P. Mack, Eurofins Agroscience Services Ecotox GmbH; T. Vollmer, Eurofins Agroscience Services Ecotox GmbH / Field Ecotoxicology; J. Illig, A. Appeltauer, Eurofins Agroscience Services Ecotox GmbH; S. Knaebe, Eurofins Agroscience Services Ecotox GmbH / Ecotoxicology Field

Micro-arthropod field tests are carried out as part of the risk assessment of plant protection products according to Römbke et al (2009). This document provides information on experimental design, but does not give indications about the available statistical power of the test or about the effect size that can be detectable in such a field study. Recently, it has been suggested (EFSA, 2013 and Brock et al., 2015) to use the minimum detectable difference (MDD) to evaluate the statistical power of aquatic test systems and validate the usage of the study for risk assessment purposes. In order to provide a better understanding of the micro-arthropod field test we carried out a retrospective MDD analysis of a series of field studies for the order Collembola. In the publications requesting MDDs, it is stated to calculate MDDs only for species. Although in reality only the lowest taxa level that can be identified is used. The reason for the identification above species level is restrains either in time, knowledge or money. We tried to use ecological groups for Collembolans in the MDD calculation besides the taxonomical groups. The impact of grouping on the statistical power in terms of MDD will be discussed. **Brock TCM, Hammers-Wirtz M, Hommen U, et al. Arthropods in off-crop meadows in Northern and Southern Europe: More comparisons of communities and responses to insecticides

S. Aldershof, Bioresearch & Evaluation; F.M. Bakker, Mitox Consultants

In earlier work we analysed NTA field studies performed with the same active substance but in different cropping systems and in different regions, to provide a first insight into the importance of geographical gradient for the response of non-target arthropod communities to insecticide exposure (1). Here we present an extended meta-analysis that includes studies with other active substances and locations, but restricted to the most vulnerable habitat type (off-crop meadows, 2). Additional analytical methods were used to compare arthropod communities and their responses to insecticides.(e.g. difference in MDD's, PRC on variances). Finally, the availability and suitability of focal species or "indicator groups" (3) for use in terrestrial arthropod community risk assessment of pesticides is discussed. Effect-driven analysis for sequentially fractionated Iranian Heavy crude oil on zebrafish embryo model

H. Shin, Seoul National University, Graduate School of Public Health / Department of Environmental Health Sciences; J. Lee, Seoul National University / School of Public Health; D. Jung, Seoul National School / Institute of Health and Environment; S. Hong, J. Khim, Seoul National University / School of Earth and Environmental Sciences; U. Yim, Korea Institute of Ocean Science & Technology / Oil and POPs research group; K. Choi, Seoul National University / School of Public Health

Crude oil is a complex mixture of chemicals. Therefore, identification of key toxic components in crude oil that cause toxic effects in biological receptors is a crucial, but daunting challenge. In this study, we investigated whether fractionation of oil by distillation is an effective method for investigating crude oil's toxicity via the effect-driven analysis. To this end, Iranian Heavy crude oil was fractionized into 34 fractions by true boiling point. Each fraction was separated at ten boiling point intervals. Zebrafish (*Danio rerio*) embryo screening test was employed for observing different toxicological outcomes (mortality, hatchability, time to hatch, and malformation rate), and was used to determine the toxicity of the distilled fractions of crude oil. There were no differences in time to hatch and embryo survival compare to control group, following the exposure to different fractions. However, malformation and larvae survival rates were significantly different among different fractions. Oil fractions with bulky aromatic compounds such as dibenzothiophene and phenanthrene, and their alkylated compounds, caused greater adverse effects such as severe yolk sac edema and heart edema. Our results show that identification of toxicological effects of different components of oil enable better understanding of adverse effects by specific crude oil components. (HS and JL contributed equally to this project). This work was supported by Korean Ministry of Oceans and Fisheries Project PM56951.

TU217

Assessing the Environmental Fate and Toxicity of Surfactants Used for Chemical Enhanced Oil Recovery (cEOR)

J. Dawick, Shell International / Shell Health Risk Science Team; D. Lyon, Shell Oil Co. / Shell Health Risk Science Team

A host of chemical enhanced oil recovery (cEOR) technologies are currently being evaluated to extend the life and maximise production of oil from new and existing reservoirs. Shell Chemicals currently produces two general classes of surfactant for enhanced oil recovery: alcohol alkoxy sulfates (ENORDET J- and A-series) and internal olefin sulfonates (ENORDET O-series). These products are currently being deployed in pilot projects around the world to demonstrate the potential of surfactant-based cEOR technology. To better understand their environmental fate and ecotoxicological effects, Shell has been commissioning a range of studies on selected products from within the ENORDET surfactant portfolio. The objective of this poster is to provide an overview of the experimental environmental fate and effects data currently available for ENORDET O-Series surfactants and how this compares with analogous classes of anionic surfactants (e.g. detergent range surfactants). The challenges faced with generating scientifically robust and relevant environmental test data for ENORDET surfactants along with potential opportunities for future research and testing will also be discussed.

TU218

Oil recovery from oil sludges obtained from different sources using surfactants in an oil sludge washing process

D.F. Ramirez Guerrero, University of Reading / Soil Research Centre; C.D. Collins, Reading University / Soil Research Centre

Oil sludges are mixtures composed mainly of crude oil, water and sediments. These are hazardous wastes generated in the petroleum extraction and refining processes and there is a need to mitigate their impact on the environment. Treatment of oil sludges to date has been focused on physicochemical remediation and bioremediation rather than oil recovery by oil sludge washing (OSW). OSW with surfactants has been recently applied for the extraction of oil for reuse. Due to the unique nature of each sludge, this study aims to compare the oil recovery among a number of oil sludges from different sources by assessing the following parameters: surfactant type, concentration, and surfactant to oil sludge (S/OS) ratio. Oil sludge samples were obtained from oil/water separation, oil drilling, following the removal of chemical additives by heating and centrifugation, and crude oil contaminated with sediment and water. Four synthetic surfactants [Sodium dodecyl sulphate, SDS (anionic); Tween 80 (T80), Triton X-100 (TX100), and Triton X-114 (TX114) (non-ionics), and one biosurfactant (rhamnolipid, RL)] were used in this study. Surfactant absolute concentrations in terms of critical micelle concentration (CMC) were established. Cyclohexane was used as co-solvent to aid in the separation of oil in the OSW. A previous study proposed that no significant differences between toluene and cyclohexane were obtained in the oil recovery, so cyclohexane was used as an alternative co-solvent due to its lower hazard. Recovered oil was measured gravimetrically. OSW parameters effects on the oil recovery rate (ORR, %) were matrix dependent ($p < 0.01$). RL and SDS had higher oil recovery rates compared with other surfactants for all sludges. In general, high oil recovery rates were obtained at a high S/OS ratio (5:1). There were no differences among surfactant concentrations ($p = 0.745$), and the highest oil recovery was obtained at 5 CMC. Recovered oil was composed mostly of C_{10}-C_{18} aliphatic fractions, and it is suitable to be reused as feedstock for heavy fuel oil production. In conclusion, RL can be used as a surfactant to recover oil from oil sludges since they have an equivalent capacity to synthetic surfactants along with a lower toxicity, additionally low concentrations can be used to reduce costs.

TU219

Adapting chemical risk assessment for water systems related to unconventional hydrocarbons

A. Faber, Copernicus Institute - Utrecht University / Environmental Sciences

Chemical risk assessment is typically done per compound with a focus on human and environmental effects. Assessing the chemical risk of unconventional drillings on water quality presents difficulties that require adaptions to this risk assessment process. The scope of this literature review is to identify and describe uncertainties and knowledge gaps of chemical risk assessment relative to unconventional drillings, and adapt the process accordingly, where possible. An extensive literature study was aimed at answering the following questions: (1) How to assess a large number of chemicals, and how complete are the databases available for physico-chemical properties and toxicological information?; (2) How applicable are available models for environmental fate modeling related to unconventional gas and oil activities?; (3) How applicable are current water quality monitoring methods to unconventional drillings? More than 7500 different chemicals are used during unconventional drillings. Advanced mass spectrometric techniques, such as liquid chromatography coupled with hybrid linear ion trap (LTQ) FT Orbitrap mass spectrometry, complemented by effect-directed analysis is the best option for broad screening of such a large list of candidates. There is however a lack of comprehensive physico-chemical and toxicological information available for assessing the screened chemicals. Moreover, available environmental fate models do not consider changing chemical behavior under high temperature and high pressure conditions. In addition, there is a need for more field-based approaches for the development of groundwater models. Current water quality monitoring is typically done at the surface and in the shallow underground, and thus does not take into account the potential for deep underground leakages. Underground leak probabilities are therefore not known. Baseline data and long-term monitoring are generally also not ensured. The tools and information necessary for chemical risk assessment of unconventional drillings on water quality are not all available. There is a need for further research into physico-chemical and toxicological information, chemical behavior under downhole conditions, and more field-based groundwater models. Baseline, long-term and deep underground monitoring would allow for a more comprehensive assessment.

TU220

Development of a Generic Exposure Scenario (GES) under the EU REACH Regulation, for substances used in high-volume hydraulic fracturing operations in response to EC Recommendation (2014/70/EU)

J. Worden, Shell International / Shell Health Risk Science Team; M. Leon Paumen, ExxonMobil Biomedical Sciences / ExxonMobil Biomedical Sciences TES Division; N. Robinson, NIKAM Consulting Limited; N. Vallotton, Dow Europe GmbH / Toxicology Environmental Research and Consulting

The European Commission Recommendation (2014/70/EU) on minimum principles for high-volume hydraulic fracturing includes, in Section 10, the requirement that substances should refer to "hydraulic fracturing" in their REACH registration dossier if they are to be used in such applications. In response to the recommendation a team of industry representatives was established that includes members from the International Association of Oil & Gas Producers (IOGP), the European Chemical Industry Council (Cefic) and the European Oilfield Specialty Chemical Association (EOSCA). The team have been working on developing a Specific Environmental Release Category (SpERC) that is based on realistic data and assumptions for hydraulic fracturing as an intended use. It can then be used in REACH dossiers as part of a Generic Exposure Scenario (GES) that describes the necessary operational conditions (OCs) and risk management measures (RMMs) which should be implemented to control the risks to the environment associated with substances used in hydraulic fracturing applications. The SpERC was developed in tandem with a background document, which provides extended information on the operational conditions, available monitoring data and assumptions that would be implicit in the final SpERC. This poster presents the SpERC that has been developed for use by industry as part of a Generic Exposure Scenario for substances used in hydraulic fracturing fluid additive products, and the conditions that are specified in the SpERC to ensure safe use. In addition,

some of the assumptions made and the details of these assumptions as presented in the background document are also reviewed.

TU221

Hot spots identification, sediment management and environmental risk assessment within a gas production field thorough a multidisciplinary approach and a novel expert decision support system

A. Gomiero, International Research Institute of Stavanger / Enviromnent; A. Dagnino, Universita del Piemonte Orientale; E. Punzo, National Research Council of Italy / Institute of Marine Sciences; P. Strafella, National Reseach Council of Italy / Institute of Marine Science; V. Salvalaggio, National Research Council of Italy / Institute of Marine Sciences; A.G. Viarengo, Universita del Piemonte Orientale / Department of Sciences and Technological Innovation DiSIT; G. Fabi, National Research Council of Italy / Institute of Marine Sciences

Offshore production of oil and gas involves some of the most advanced and massive engineering projects. Such industrial activities may induce both occasional as well as long lasting environmental impacts in the aquatic ecosystem, often acting in combination with other environmental stressors. Nowadays, complex and advanced multidisciplinary monitoring approaches combining chemical, ecotoxicological and ecological data are available worldwide. These collect large dataset of different information, which need to be correctly inferred and integrated to provide a comprehensive knowledge of the environmental health status. Indeed, a management focused on impacts of a single stressor is inefficient and often ineffective because co-occurring human activities lead to multiple simultaneous impacts on communities and individual species. Thus, a quantitative assessment of the spatial patterns of all human uses of the marine aquatic environment and their cumulative effects is needed for implementing the ecosystem-based management, the ecosystem services conservation and the sustainable exploitation of natural resources processes. In this case study, we apply methods developed to map cumulative impacts in sediments collected during the key steps of the set up and the production phases of a gas platform located in the Adriatic sea. Sampling sites are classified by means of comparing chemical concentrations with effect-based target values. The level of each contaminant and the combined toxic pressure are used to rank sites into uncontaminated, mildly and heavily contaminated. According to a triad based approach, in contaminated sediments, an environmental risk index is determined by means of integrating chemical data with ecotoxicological and ecological parameters. Furthermore, a sediment risk index is computed from combining chemical and ecotoxicological data. At sites identified as moderately contaminated, sub lethal stress index are integrated with chemical data into a biological vulnerability index. In the meantime, potential risk for human health is assessed in selected stations by integrating genotoxicity biomarkers. Finally, geostatistical tools are applied to show the space and time related risk index distribution.

Development, standardization and implementation of LCA and integration with economics for transportation infrastructure and operations (P)

Noise impact category implementation in an LCA software tool to assess road restorations

D. Garrain, CIEMAT / Energy Energy Systems Analysis Unit; E. Pellón, SoildForest; I. Herrera, CIEMAT / Energy Dpt   Energy Systems Analysis Unit; R. Jiménez, Solidforest; Y. Lechon, CIEMAT / Energy Dpt   Energy Systems Analysis Unit

Several difficulties have arisen in the inclusion of road traffic noise as an impact category within the LCA method. There are many reasons for this marginal treatment of noise in LCA. Main reasons are related to the special characteristics of noise as a pollutant, such as the site-dependency of impacts, the human perception issues or the non-linearity of impacts and limited availability of data, which have hindered its inclusion within this method. Nevertheless, some specific studies within the LCA framework aimed to better accommodate the assessment of its impacts have appeared so far. Most of them have been focused not just in traffic noise but also in noise from any other source, from Müller-Wenk (in the 90s) to more recent authors, such as Franco, Cucurachi, Moliner or Althaus (in the last 10 years). This study presents how the endpoint methods of Moliner and Franco,considering the human health impact of noise could be implemented in an LCA software tool, named Air.e LCA®. This proposal has been developed under the framework of a new Spanish R+D+I project whose main aim is to research and develop new materials and techniques to improve the road restoration activities. The fact of including the noise impact assessment will contribute to compute the benefits to human health of developing and using new sound-dampening, sound-reduction or anti-noise materials into road surface.

TU223

Environmental assessment of EAF steel slag use in road

W. Chebbi, IFSTTAR; o.Y. marzouk, Cerema / Dter Centre Est DL Autun; M. DAUVERGNE, IFSTTAR; j. agnès, IFSTTAR / Loire Atlantique

Electric arc furnace (EAF) slag is a non-metallic by-product of steel production by electric arc furnace process. About 12 million tons of steel slag are produced annually in Europe. Considered as waste for a long time, this industrial by-product is increasingly used in civil engineering applications as its valorization allows a number of benefits such as the conservation of natural resources, the reduction of waste storage volumes, the decrease of material construction cost and transport demands and the promotion of local economy. The environmental assessment of EAF slag recycling using life cycle assessment (LCA) in road is investigated in this paper. Generally, in the LCA framework, the environmental assessment of recycling waste don't takes into account the phases of life cycle corresponding to stockpiling and use, as they are considered to have no impact, only waste processing is counted. Thus, we propose a method to assess recycling of EAF slag in road considering the phases of production of EAF salg (for recycling purposes), stockpiling (lixiviation test), transport (30 km) and use in road (uncovered 10-15 cm thick road layer) and to compare this scenario to natural sand in order to evaluate the various impacts obtained for each step of the EAF slag life cycle and discuss the interest of various solutions considering both toxicity and ecotoxicity indicators. Furthermore, the calculation for use phase based on experimental data (results from percolation test) is compared to its calculation based on Ecoinvent data which take into account the total content (x-ray fluorescence) and a transfert factor (from Ecoinvent data base) for short term, in order to seek if the results are in the same range or not.

TU224

Life-cycle GHG emissions of alternatives for collecting and transporting municipal solid waste: The case of a Spanish community

D. Garrain, CIEMAT / Energy Energy Systems Analysis Unit; I. Herrera, Y. Lechon, CIEMAT / Energy Dpt   Energy Systems Analysis Unit

Currently, the communities and municipalities are increasingly aware of managing a clean and sustainable transport in their mobility services. Thus, it is usual (and almost mandatory) to include aspects for improving sustainability in tenders for contracts and execution of public services. More specifically, in the case of collecting and transporting municipal solid waste several key aspects are important to be considered in order to reduce emissions, energy consumption and other environmental issues. In this context, both the use of alternative fuels and the introduction of electric vehicles are positively valued in order to achieve environmental improvements and energy savings. This study presents an assessment of different proposals for introducing the use of alternative fuels (such as liquefied petroleum gas, natural gas and biofuels instead of conventional diesel) in the vehicle fleet of a Spanish small urban community to collect and transport municipal solid waste. The possible use of hybrid and electric vehicles has also been considered. The results show an important decrease in GHG emissions when natural gas is used as fuel. Nevertheless, this measure entails an increase of other harmful gases, such as CO or VOCs, when compared to other alternatives. Finally, in order to complete the environmental assessment of the whole activities regarding the management of municipal waste, the quantification of annual GHG emissions of the processes of washing containers and pneumatic collection of waste have also been included. These activities could be responsible for the 10 to 40% of total GHG emissions of the waste management in the community.

TU225

External costs of electrification of road transport: approach and setting-dependency

P. Preiss, T.M. Bachmann, EIFER - European Institute for Energy Research / Urban systems group

The use of electric vehicles in comparison to internal combustion vehicles is a typical example for burden shifting from the use phase to upstream processes, i.e. fuel supply in the form of electricity. Within the collaborative EC project SCelecTRA (2012-2015), funded within the frame of the Electromobility+ Initiative, the following steps in the assessment chain were addressed: 1) definition of scenarios to enhance electromobility uptake in Europe in the mid to long term; 2) modelling their impact on the power and transport sector with the aid of the TIMES PET36 model, distinguishing 36 European countries, different means of power production and different transport demands; 3) assessing the environmental implications particularly in terms of emissions and abiotic resource uses following LCA principles, and 4) monetary valuation mainly of impacts due to classical air pollutant emissions (external costs). The study undertook to establish a set of new regionally specific unit damage cost factors (UDF) for the characterisation of human health impacts in LCIA including weighting that aim at being setting-dependent, as suggested by the expert panel of the Basel workshop (Fantke et al., 2015). To this end, pre-calculated external cost factors have been obtained from the literature. For power generation, a distinction is made between different countries and emission heights (above or below 100 m or undetermined). For transport-related emissions, external cost factors specific to countries and/or setting (e.g. population density) are used to the extent available. While relying on LCI data and energy system analysis results from project partners, external costs for the different scenarios were quantified. Comparing the overall UDFs obtained this way with those derived generically for the EU27 shows a variability of about a factor of 0.2 up to 2. The use of country-specific characterisation factors (UDF) instead of EU average values for a European wide assessment of energy and

transport activities thus leads only to a negligible difference in the results. The relevance of using country-specific or generic UDF also depends on the scenario analysed.

TU226

Building a common base for LCA benchmarking of Li-Ion traction batteries

J.F. Peters, KIT Karlsruhe Institute of Technology / Helmholtz Institute Ulm HIU; B. Simon, Universite de Sherbrooke / Department of Civil Engineering; G. Rodriguez Garcia, Helmholtz Institute Ulm / Systems III; M. Weil, Karlsruhe Institute of Technology KIT / Institute for Technology Assessment and Systems Analysis ITAS

Although the environmental impacts of e-mobility are usually dominated by the use phase, the production of the battery also plays a significant role, especially when it comes to choosing the most adequate battery type for a given application. Numerous studies quantify the impact of the battery production process along the life cycle for different battery chemistries. Nevertheless, these studies use different impact assessment methods and different approaches for modelling key parameters like energy demand for cell manufacturing or electricity mixes. On the other hand, the outcomes of these studies are highly sensitive on these parameters, why a direct comparison of different studies is critical. A common basis for comparing the environmental performance of different alternative Li-Ion battery chemistries is not given, but seems very desirable to support decisions of technology developers. Based on a review of all available LCA studies on Li-Ion batteries, the discrepancies in the key parameters between these studies are identified and their impact on the outcomes of the studies pointed out. The existing primary inventory data (LCI) for the principle Li-Ion battery chemistries are then recompiled and average values used for these parameters. In this way, the environmental impacts associated with the production of different battery chemistries are assessed on a common base. This provides an improved comparability between studies and allows for a technology benchmarking of different Li-Ion battery chemistries. Furthermore, a sensitivity analysis is done by varying the values of the key parameters within the identified range, pointing out the relevance of each of the parameters and the uncertainty in this regard. It can be observed that different assumptions made for these parameters can overrun the differences between battery chemistries completely. Especially the approach for modelling the cell manufacturing energy demand influences the results significantly. Thus, putting existing LCA studies on a common base is essential for battery technology benchmarking and avoids erroneous conclusions when comparing different Li-Ion battery chemistries regarding the impacts associated with their production and with their use in electric vehicles.

TU227

Regionalized life cycle impacts of worldwide coal transportation from mines to power plants

C. Oberschelp, ETH Zurich; S. Pfister, S. Hellweg, ETH Zurich / Institute of Environmental Engineering

Motivation Coal-fired power production is known to substantially contribute to global health problems and environmental damages. Driven by consumer demands, these are caused by pollutant emissions occurring along its entire supply chain including transportation. Due to growing world-wide energy consumption, this technology remains essential for reliable energy supply at competitive costs in most countries around the world. Thus incremental improvement of the coal supply chain is a promising opportunity for mitigating harmful impacts beyond improvement of energy efficiencies of power plants. One key problem for allocation of resources to these improvements is insufficient assessment of the regional resolution of emissions and impacts. These differ substantially depending on the transporting vehicles and environmental conditions. As such, species-rich habitats or densely populated regions are often particularly sensitive to transportation emissions compared to remote locations. This aspect has not been covered sufficiently by current publications yet. The present work aims at closing this gap by combining various types of regionalized information and calculating region-specific impacts. *Methods* Power-plant-specific consumption data is merged with global coal transportation routes to identify hotspots of the coal supply chain. Impacts on humans and ecosystems are quantified with spatially-explicit characterization factors by regionalized life cycle assessment (LCA). The required data for power plant coal demands is calculated from the WEPP database which is linked to international coal trade via multi-regional input-output (MRIO) data from Exiobase. This in turn is connected to coal mining data with regional coal specifics and explicit mine locations to determine transportation profiles and distances for different types of coal. *Results and conclusions* The results highlight hot spots in global coal transportation and show where modernization of vehicle fleets and restructuring of material flows is most relevant. As such the results are a step towards a fully regionalized inventory of the global energy sector and represent a guiding example for expanding regionalized life cycle assessments to transportation systems.

TU228

Evaluation of innovative products and processes for road infrastructure projects towards the LCE4ROADS Certification System methodology.

R. FERNANDEZ, E. GUEDELLA BUSTAMANTE, A. ALVAREZ DE CASTRO, ACCIONA Infrastructure; C. BARTOLOME, IECA; J. MELERO CORELL, BAST; G. LEEGWATER, TNO

Although there are many initiatives in the market capable to assess sustainability aspects for roads, many lack of a holistic view of sustainability because some of the current approaches do not cover all life cycle phases or all sustainability pillars and focus mainly on environmental aspects. Some examples are Greenroads, Envision and Invest, in the US, and Ceequal (UK), and the Dutch CO2 Performance Ladder in Europe. The purpose of this paper is to show the results achieved on the development of a new sustainability certification system for roads named "LCE4ROADS", currently under way as part of the FP7 project "Life Cycle Engineering approach to develop a novel EU-harmonized sustainability certification system for cost-effective, safer and greener road infrastructures (GA No 605748)". LCE4ROADS is based on a Life Cycle Engineering (LCE) approach: all the aspects of sustainability (Environmental, Economic, Social, and Technical) are considered with the final goal of creating a holistic and EU-harmonized methodology for assessing the sustainability of both new and rehabilitation/maintenance road projects, works and products. The proposed certification system relies on current EN and ISO standards and considers previous developments from other research projects like MIRAVEC, EVITA, COST 354 among others. Key aspects at European level such as resilience to Climate Change and the implementation on TEN-T corridors are also considered within the certification system. This paper aims also to show the first results of using the LCE4ROADS Methodology for evaluating different innovative products and processes for road infrastructure projects. This is line with one of the main purposes of LCE4ROADS certification system which is to provide support and guidance to relevant industry stakeholders on the selection and implementation of technologies that could enhance sustainability of road projects. The results show that there is difficulty in achieving a positive result on the environmental domain without negatively influencing the others, which supports the assumption that real sustainability actions should be based on trade-offs among all the sustainability domains. In conclusion, the LCE4ROADS methodology, together with its associated software tool and guide, becomes a solid method for assessing road projects and products in terms of sustainability as well as for supporting future procurement and GPP processes in Europe.

TU229

Life cycle assessment and cost benefit analysis for carbon capture and storage

a. edahiro; N. Itsubo, Tokyo City University

Recently, a variety of mitigation and adaptation measures on climate change have attracted attention. In particular, CCS are growing interests from year to year. According to the roadmap shown by the International Energy Agency (IEA), many of mitigation procedures have been evaluated compare their priority. Many studies, evaluating environmental performance for CCS using LCA has been performed. However, most of studies focus on only GHG emission. On the other hands, there are few studies which apply the comparison and verification including the other types of environmental impact and cost analysis. Considering the above point, in this study, it was conducted an exhaustive evaluation including environmental influences such as SOx and NOx. Further, we examined the usefulness of mitigation measures and the relationship of trade-off of between environmental impacts by calculating the total cost results including the external costs.

TU230

Environmental impact assessment of rail freight intermodality. Energy related emissions

A.L. MERCHAN, University of Liege / Chemical Engineering PEPs; S. Belboom, University of Liège - Chemical Engineering / Chemical Engineering PEPs; A. LEONARD, University of Liege / Dpt of Chemical Engineering PEPs

BRAIN-TRAINS is a project supported by the Belgian Federal Government that deals with the possible development of rail freight intermodality in Belgium, approaching the problem from an interdisciplinary perspective. Life Cycle Assessment (LCA) methodology will be used to analyse the sustainability impact of rail freight intermodality for three divergent Belgian scenarios by 2030. This objective is directly linked to the goal of increasing the rail market share by 2030, stated by European Commission's White Paper on transport (2011). The LCA rail freight system is divided in three sub-systems: rail transport operation, rail infrastructure and rail equipment (locomotives and wagons). The life cycle phases of construction, maintenance and disposal of rail infrastructure and manufacturing, maintenance and disposal of rail equipment are analysed. The sub-system rail transport operation includes direct and indirect processes that are connected with the train activity. As direct processes, we consider the specific energy consumption per travelled distance, the amount of transported freight expressed per tkm (both depending on the train traction, thus considering diesel and electricity traction separately), the direct emissions to air related to the diesel combustion in locomotives per tkm and to soil from braking and lining (iron abrasion of rail tracks, wheels, brakes and overhead contact lines) and the people exposed to noise due to rail freight transport activity. Indirect processes include the upstream emissions and energy consumption related to the production and distribution of the diesel and electricity used in rail transport will also be determined. Appropriate emission factors will be calculated to determine the direct and indirect emissions. The transport emissions related to the energy consumption during the rail transport activity will be determined considering the predicted transport volumes in a time horizon 2030.

TU231

The model for optimal transport selection based on multi-criteria decision making and life cycle assessment

B. Agarski, Faculty of Technical Sciences, Novi Sad / Department of Production Engineering; I. Budak, University of Novi Sad, Faculty of Technical Sciences / Production engineering; D. Vukelic, Faculty of Technical Sciences / Department of Production Engineering; K. Szita Toth, University of Miskolc / Institute of World and Regional Economics; J. Hodolic, Faculty of Technical Sciences, University of Novi Sad / Department of Production Engineering

Considerable amounts of resources are used by transportation vehicles throughout their whole life cycle - from design and production, over maintenance and operation to the end of life stage. When considering transport selection problem, nowadays environmentally conscious companies are paying special attention to environmental burdens where life cycle analysis (LCA) presents valuable assessment tool. Selection of optimal transport alternative for both - employees and goods, that considers the life cycle environmental burdens is a multi-criteria decision making (MCDM) problem. This paper proposes the model for optimal transport selection based on MCDM where the environmental aspects are considered through the life cycle perspective. An illustrative example has been provided for the verification of the proposed model. The transportation problem evaluated here is of a company that needs small packages to be delivered from point A to point B in urban environments. Proposed MCDM & LCA model considers environmental, economic, social and technical aspects for selection of optimal transport expressed through defined criteria. Environmental criteria is expressed through LCA of delivery vehicle considering the following processes: production, operation, maintenance and end of life. Economic criteria is presented through the travelling cost, as social criteria the personal subjective judgement is included, while in technical the delivery time criteria (expressed through the period of time needed for package delivery) is the most important one. The considered alternatives include: transport by foot, bicycle, scooter, car, and public transportation (bus and tram). The aim of the proposed MCDM & LCA model is to assist companies which activities are occasionally connected to just-in-time delivery business, in their environmental impact decrease.

TU232

Systematic LCA method in automotive sector

A. BOUTEILLE, Renault; P. Osset, Solinnen; M. Pelissard, Renault; D. Bauchot, Solinnen SAS; J. Beaulieu, S. Morel, Renault; C. Beaudard, Solinnen SAS

Life Cycle Analysis (LCA) is often viewed by companies as the most relevant tool to open the dialogue with stakeholders (Schmidt 2010). But on the other hand, it is percieved as a time-consuming, difficult to implement, with short-lasting relevance of its results and, above all, costly approach. The requirement of critical review for comparative LCA to communicate results to the public ,often leading to additional delays and costs, can also discourage to adopt this approach. In parallel companies are facing more and more demanding environmental regulations and standards such as the Euro regulation in the transport sector, as well as regulations that require robust communication on the environmental performance of marketed products. For example, the ongoing Product Environmenal Footprint (PEF) experimentation should lead to new regulations on environmental footprint communication based on LCA approach, that are expected in 2018. In that context, large companies have integrated environmental criteria (regulatory requirements as well as internal objectives) in their core business quality approach leading to the definition of very detailed processes that are automated/computerized in order to be easily repeated for any product. Thus, the group Renault endeavours to carry on on this environmental integration into the quality approach and to develop a systematic LCA method with the following objectives of (1) communicating on the environmental footprint of their product in an more efficient, rapid and robust manner, (2) ensuring the quality and reliability of data (notably regarding geographical, technological and time representativeness), (3) being able to improve constantly the approach and the modelling. The development of the systematic LCA method in Renault started in 2011 when Renault renewed its calculation model during the study of an innovative product, the electric vehicle. This first step of the model was assessed by a particularly skilled panel which cumulate 50 years of experience (Morel 2014) and set the baseline for further studies. The second step of the model developed in 2014 aims at comparing any new vehicle with its former model. The current model enables to perform a comparative study in about 15 days, with a critical review performed in 2,5 days on a 1,5 month period. The extended abstract described the developed method. The oral presentation with two speakers, one of Renault and one of Solinnen present the method from each point of view.

TU233

Life cycle assessment of underground construction Tunnel case study

Y. AUDI, IFSTTAR; A. Jullien, IFSTTAR / DAEI; M. DAUVERGNE, IFSTTAR; L. D'ALOIA SCHWARTZENTRUBER, CETU; A. FERAILLE, ENPC

In a global context of urban density, the underground space can be an opportunity for developing further cities with restricted spaces, and respecting at the same time the requirements of sustainability which lie strongly today to urban projects. The underground developing in urban zones provides an important space which is characterized by its ability to offer new spaces, separate functions, protect from negative impacts, in addition to many environmental and social benefits. In parallel, the construction and the exploitation of the underground facilities can significantly affect the environment, but can otherwise provide energy efficiency due to the thermal isolation or to the energy recovery. In return, these facilities can represent a significant financial investment, generally determined in the decision-making process. This article aim is to: I) propose a characterization methodology of underground structures depending on theirs geometry, functionality and method of construction. II) Propose a methodological approach for the evaluation of their environmental impacts. This approach is based on a case study. It is a linear underground structure; that serves multimodal displacement (light vehicles, public transport, cycling and pedestrians). This evaluation is performed by environmental impacts which are obtained from life cycle assessment (LCA): energy consumption, global warming, photochemical ozone creation potentials, toxicity, and acidification. The results serve also to compare the performances of this structure to those of alternative surface solution, ensuring the same service. The question of impact's allocation to users of this multimodal transport infrastructure is also envisaged, taking into account the multimodal displacement in our case study. The results of allocation allow demonstrating the importance of mode-phase of life cycle to evaluate the environmental profitability, and then evaluate other sustainable development indicators, that will bring to think about indicators that provide results to enhance the benefits of underground construction. This initial work fits with a thesis IFSTTAR-CETU PhD, supported by the national project "*VILLE 10D-VILLE D'IDEES www.ville10d.fr*" about the design and the planning of the underground spaces to develop sustainable cities.

Expanding LCA: looking at organizations and at new policies (P)

TU234

EXPERIENCES IN THE APPLICATION OF ORGANIZATIONAL LIFE CYCLE ASSESSMENT IN MEXICO

M. Gomez, Instituto de Ingenieria UNAM; L. Güereca, Engineering Institute Universidad Nacional Autónoma de México / Environmental Engineering

The evaluation of the environmental performance has been a strategy for setting goals related with the continuous improvement in organizations, but these evaluations are usually partial, because normally considered a specific facility and a reduced period. The Organizational Life Cycle Assessment (O-LCA) permits the determination of environmental indicators scientifically stronger because they consider all products and/or services of an organization, including the inputs and outputs throughout the life cycle of all associated processes. Taking into account the above, this paper presents the experiences in the implementation of the O-LCA methodology in the Central Bank of Mexico. The scope of this study concerns the banknotes factory whose function is the production of all denominations of Mexican bills. The system boundary includes all departments that are part of the factory (direct activities), the steps related to the supply of raw materials (upstream activities) and the steps related to the distribution, use and end of life (down-stream activities). For the definition of the reporting unit it took into account the production in 2013 with all related information. The assessment of environmental impacts was conducted with ReCiPe method and Ecoinvent 3.1 database, using Umberto 7.1 software. The impact categories analyzed were: agricultural land ocupation, climate change, freshwater eutrophication, human toxicity, ozone layer depletion, photo-oxidant formation, acidification and water use. The results show that for all the categories analyzed, activities upstream and down-stream together are generating the highest environmental impacts. The analysis of the direct activities shows that the departments of printing, distribution and administrative services presents the highest environmental impacts. It can be concluded that transportation, in direct and indirect activities, generates significant impacts, therefore improvements are recommended in this sector. The application of this methodology gives as a result a lot of potential improvements throughout all stages of life cycle. Scoping is an issue that can be discussed from other experiences in the application of O-LCA, since in this case the departments with the most significant environmental impacts were considered and not the organization as a whole, due to the rigorous level of detail and the large amount of data required in this type of LCA.

TU235

The Organisation Environmental Footprint (OEF) pilot on copper production

L. Zampori, European Commision DG Joint Research Centre / Institute of Environment and Sustainability; R. Pant, European Commission / Institute for Environment and Sustainability; S. Sala, European Commission - Joint Research Centre / Sustainability Assessment unit

In the context of the "Building the Single Market for Green Products" initiative of the European Commission (COM 2013 196 final and related Recommendation 2013/179/EU), which proposes a set of actions to overcome confusion of consumers due to the stream of environmental information they receive, two Organisation Environmental Footprint (OEF) pilots are currently ongoing (copper sector and retail) and they are expected to deliver the final OEF sector rules (OEFSR) by end 2016. The OEF pilot on copper production is led by the Joint Research Centre (JRC) and it is currently supported by leading European industries in the sector (Aurubis, KGHM and Outotec). Copper is a key enabler of resource efficiency, as it enables the recovery of several different products that can be associated to its production. Copper smelters can process both primary and secondary raw materials, therefore they are both at the beginning and at the end of the life cycle of products. The product portfolio of a copper producing company covers many products, all directly linked to copper production: copper cathodes, anodes and blister, sulphuric acid, iron silicate, anode slime, $NiSO_4$, $CuSO_4$, silver, gold, PGM concentrates, lead, Pb-Sn alloys, tin, crude selenium and tellurium. An organisational LCA, compared to a product LCA, considers the organizational activities as a whole: this approach allows to identify what are the most important environmental issues both in the sector and the organisations itself. It is useful for an organisation to rely on a robust measurement tool, such as the OEF, which can be implemented in other environmental management schemes (e.g. EMAS), to allow prioritisation of environmental management actions, both within the organisational boundaries (i.e. direct activities) and outside (i.e. upstream and downstream, indirect activities). The focus, therefore, is mainly on performance tracking and improvement. Results can be communicated depending on the target audience, and they can be used to provide information to investors, stakeholders and public administration. The first draft of the OEFSR on copper production was approved in July 2015 by the Environmental Footprint-Steering Committee. The ongoing work within the pilot and the final OEFSR will show opportunities and limitations of the methodology.

TU236

Evaluation of Natural Capitals for organizations Considering Life Cycle of Perspectives

S. Suguri, N. Itsubo, Tokyo City University

In recent years, environmental evaluation of the organizations using the framework of LCA is now paid attention internationally. Although the interests in CSR and triple bottom line increase, the development of assessment method covering 3 aspects (environmental, economy and society) of organization is still limited. On the other hand, international organizations such as the World Bank and the United Nations discuss about framework of sustainability and indicators of subcategories. These outputs would be useful to apply for the development of LCA for organization considering all aspects of sustainability. In this study, we develop a research framework of organizational Life Cycle Assessment using Genuine Saving proposed by the World Bank. Genuine Saving is a method which evaluate increased or decreased of capitals. Genuine Saving can be obtained by the summation of savings, education payment the loss of natural capital including forest, minerals, and fossil fuels and environmental damages caused by global warming. We adopted Input-Output analysis and Life Cycle Impact Assessment to evaluate these above elements and aggregate them to consider the all attributes of sustainability. We discussed the feasibility to construct a framework of Organization LCA proposed by this research based on the case studies for Japanese companies.

RECO-INNO: An evaluation model approach for eco-innovation and its impact in the business strategy

F. Coca, I. Bosch-Frigola, Universidad San Jorge; M. Pino, San Jorge University / Facultad ciencias de la salud; S. Scarpellini, CIRCE

The scarcity of natural resources and the consequences of environmental challenges affect companies that are looking for more efficient processes and sustainable products. These factors strengthen the consolidation of the eco-industry and the implementation of Eco-innovation.\n Eco-innovation improves the technology upgrading, products and services linking the binomial firm-innovation and cost savings. It is related to business models based on a new strategy to incorporate sustainable development in business, reducing environmental impacts and saving raw materials through innovation initiatives. During this last decade, the European Union has led to the improvement of environmental and competitive position of European industry with new management models and the latest technological developments. With nearly 200 million Euros, it has established the objective of promoting eco-innovation within its Framework Program for Competitiveness and Innovation. The aim of this study is to define the company's code of conduct in a sample of eco-innovative companies through the development of models based on quantitative methods. Principal determinants of eco-innovation throughout their organizational life cycle are analyzed for integration of structural variables and they are applied to the appraisal of principal economic, social and environmental outputs in business. In order to carry out the study, a sample of 100 Spanish companies has been analyzed. Data have been obtained through a questionnaire in which variables have been identified to reflect the decision about eco-innovation and its principal determinants (technological options, investment, structural and environmental variables). The keystones of the business strategy related to eco-innovation have been analyzed as well with principal business results and the company's environmental management factors. The results gained reflect an in-depth analysis of the situation of the level of penetration in Spain of eco-innovation among companies, in order to overcome principal barriers.

How sustainable are WEEE? A review of LCA applied to waste from electric and electronic equipment

G. Rodriguez Garcia, Helmholtz Institute Ulm / Systems III; J.F. Peters, KIT Karlsruhe Institute of Technology / Helmholtz Institute Ulm HIU; M. Weil, ECT Oekotoxikologie GmbH / Institute for Technology Assessment and System Analysis ITAS

The increased use of electric and electronic equipment (EEE) has turned their waste into a pollution problem worldwide. As a complex environmental burden, over the years the management of waste from electric and electronic equipment (WEEE) has been the object of a number of Life Cycle Assessment (LCA) studies. For this presentation, we reviewed 47 LCA publications evaluating end-of-life alternatives for WEEE. Our initial point of interest were recycling technologies, but was soon expanded to include the whole waste management: collection and transport, alternative treatments—landfill and incineration—as well as waste prevention strategies. The reviewed publications focus more on products than on processes, being more interested in the impacts of a given waste flow than on a given treatment technology. Most of them take into account the whole waste management—usually considered as transport and treatment, but studies evaluating only recycling technologies are also common. Publications where recycling is confronted with other treatments are less abundant and there is even fewer taking into account waste prevention strategies, either on their own or as an alternative to treatment. We only took into account studies that covered the whole life cycle if they had a particular focus on waste management. Those that did, concluded that waste management was not the most polluting stage. The environmental importance of waste management--namely of recycling—was due to the potential recovery of valuable materials—metals, plastics, and glass in particular—could avoid the extraction and processing of new materials. However, recycling is not necessarily the greenest alternative. Long-distance transport can make landfilling more attractive and there are several waste prevention schemes that, at least in the short term, could be more beneficial to the environment than recycling. Because of that, when conducting an LCA on WEEE management strategies we should take into account more scenarios than an alternative recycling technology.

TU239

State of the art on coupling input-output table with material flow analysis in order to evaluate environmental impact of metals in an economic system

A. Thevenot, Université de Bordeaux; P. Loubet, Université Bordeaux; G. Sonnemann, University of Bordeaux / The Life Cycle Group CyVi

In a context of increasing **global demand** of metals (e.g., for building and high technologies), European countries, especially France, widely depend on foreign imports. This situation implies a real risk of physical or economic disruption of supplies. The European commission registered critical materials in a list for which data concerning flows should be improved and reliable. However, it is complex to calculate material balance of a substance at a geographical scale (including import, export, waste, stocks, recycling). Improving the knowledge in material flows in an economic system would contribute to evaluate the potential of secondary raw material sources.Currently, two main methods are used to map the flows of metals: **Input-Output Tables** (IOT) which is a top/down approach and **Material Flows Analysis** (MFA) which is a bottom/up approach. The **IOT** represent the exchanges in monetary value allocated to different economic sectors. These values are contained in a square matrix showing the monetary exchanges of materials between the activities. After conversion from price flows to physical flows, we obtain physical input-output tables (PIOT). Nevertheless, the stocks and waste flows cannot be reliably calculated with these tables. On the other hand, the aim of **MFA** is to quantify the whole flows (inputs, outputs, stocks) of a substance (or a product) at a process scale with defined boundaries. However, we do not necessarily know the flows for each process, and missing values would generate inconsistencies. A reliable "mapping" of metal flows from production to final use could be obtained by coupling these two methods. Eventually, life cycle assessment (LCA) can provide **environmental impact** regarding MFA results in order to obtain a multi-criteria analysis, which depends not only on resources flows. We provide a first attempt for coupling PIOT and MFA in order to evaluate **copper flows** in France.However, such an approach deal with various data from statistic studies, custom services, professionals or scientific research. These data can be restricted for some materials.It is needed to reconcile the data from PIOT and MFA for specific materials. A methodological challenge is to develop an **innovative approach** for improving the coupling of these two methods and to reduce the uncertainties of initial data. From the resulting flow mapping, we will be able to calculate more effectively environmental impact of metals.

Eco-design of packaging for a circular economy in the food canned industry

J. Laso; M. Margallo, R. Aldaco, J. Celaya, University of Cantabria; C. Gazulla, ESCI; A. Bala, Escola Superior de Comerç International (ESCI); P. Fullana, Universitat Pompeu Fabra (UPF) / UNESCO Chair in Life Cycle and Climate Change Escola Superior de Comerç Internacional ESCI; A. Irabien, University of Cantabria / Department of Chemical and Biomolecular Engineering

Since the industrial revolution, waste has constantly grown. This is because our economies have been dominated by a one-way or linear model of production and consumption that follows a "take-make-consume and dispose" pattern of growth in which goods are manufactured from raw materials, sold, used and then discarded or incinerated as waste. [1]. For this reason, in 2014, the European commission (EC) published a communication on the circular economy which stimulates innovation in recycling and reuse, limit landfill, reduce losses of resources and create incentives for behavioural change, turning waste into a resource as part of "closing the loop" in circular economy systems [2]. In the packaging sector, the circular economy model is about more than just recycling. It handles all stages of product´s lifecycle, namely: its design, production, distribution and use, but also its recovery. Regarding the product design, eco-design takes the environment into account reducing the product´s negative impact on the environment throughout its lifecycle while maintaining the same level of quality [3]. In this context, this work aims to apply the concepts of circular economy and eco-design under a life cycle approach to the seafood sector and, in particular, to the canned anchovy industry. This sector generates a high amount of packaging wastes of several sizes (0.05, 0.5 and 1 kg) and materials (glass, aluminium, tin, paper, cardboard, plastics, etc.). The life cycle assessment (LCA) of the production of one can of anchovy from cradle to gate revealed that the manufacture of these packages has the highest environmental impacts and, thus recycling these materials would improve the environmental performance of the system. For that reason, this work proposes a methodology that combines the circular economy and eco-design concepts to reduce the environmental impacts of food canned industry. [1]. TU241

LCA of Rare Earth Magnet Recovery in the REMANENCE project. The role of LCA in the development of recovery technologies; allowing circular economy of WEEE.

R. Villalba, Leitat Technological Center / Sustainability Unit; M. Escamilla, Leitat Technological Center / RD Safety Sustainability Division

REMANENCE is an ambitious project designed to dramatically increase the amount of rare earth materials recovered and remanufactured from existing waste streams, which contribute to the technology development necessary to make possible circular economy across EU. Co financed by the Seventh Framework Programme, the project brings together European industry and academia across the supply chain to develop innovative technologies, business models and market information required to exploit this valuable resource and reduce dependence on primary sources. Within this context, new and innovative processes are being demonstrated for the recovery and recycling of rare earth (RE) containing neodymium iron boron magnets (NdFeB) from a range of Waste of Electrical and Electronic Equipment (WEEE), and resulting in the development of new recovery technology able to recover RE material in a form that could easily re-enter the primary magnet manufacturing production process, so providing large energy savings and material costs. REMANENCEwill provide a secondary source of materials for the EU, large enough to supply the entire EU bonded magnet manufacturing industry and a significant proportion of the EU's high value sintered magnet production (1500-2000Tpa). Among others environmental indicators, it is expected than the introduction of the RE magnetic recovered and recycled material into the manufacturing process will significantly reduce the energy cost and environmental impact of these replaced materials. Thus, the recovery and reprocessing of RE magnetic materials is foreseen to reduce energy consumption by more than 95% when compared to emissions from primary production (mining, separation, purification and manufacturing) of RE. The analysis of such environmental indicators is possible through the use of Life Cycle Assessment (LCA) methodology, which allows comparison between the environmental impacts of the recovery technologies developed in the project versus the conventional extraction of virgin material, two very different ways of obtaining the RE material necessary in the primary magnets manufacturing. The LCA results will demonstrate how the REMANENCE technology is contributing to close the loop and boost business related to WEEE.

TU242

Recycling Rare Earth Elements

G. Bailey, KU Leuven / Material Sciences; K. Van Acker, KU Leuven

Many rare earth elements (REEs) are used in clean technologies such as wind turbines and in permanent magnets found in electric vehicles. Today, the recycling rate for rare earth elements is less than 1%. It is expected that in the coming years, demand for rare earths will grow as the European economy makes the transition toward high-tech and green products. However, as the virgin REEs market is monopolized by China making REE prices highly volatile, and as the environmental impact of REE mining is large, the recovery of the REEs is extremely important for both economic and environmental reasons. As highlighted by the European Rare Earths Competency Network (ERECON), recycling of rare-earth magnets should receive top priority. The following study will provide summary of the current recycling techniques discovered for REEs in permanent magnets. This analysis is executed by means of a literature review and interviews with experts from both industry and academia. In addition, the performances of current recycling methods are evaluated from both an environmental and economic perspective. For this evaluation data was gathered through numerous Life Cycle Assesment (LCA) and Life Cycle Costing (LCC) experiments on REEs in permanent magnets. Neodymium is the most common rare earth element found in permanent magnets and will be assessed to determine where the greatest environmental impacts, or hot spots, in the recycling routes occur. Different impact factors are calculated, enabling detection of potential new recycling routes. Since permanent magnets contain a high concentration of REEs, a reduction in the demand for virgin sources has the potential to shift Europe's reliance on Chinese exports, as well as lowering the environmental impact generated.

TU243

Consequential Life-Cycle-Assessment as policy-support tool to promote green concretes

A. Di Maria, KU Leuven / MTM; K. Van Acker, KU Leuven

The manufacturing of Ordinary Portland Cement (OPC), normally used as a binder in concrete production, is responsible for 5% of global carbon emissions. Potential sustainable alternatives, namely "green concretes", are currently studied in scientific literature. In green concretes, OPC is replaced with by-products coming from other industries. At present, however, the economic and environmental consequences of the introduction of green concretes into the market are not clear yet. This paper aims at filling this gap by using a Consequential Life Cycle Assessment (C-LCA) for the case of green concrete made from Stainless Steel Slag (SSS), with a focus on the Flemish market (in Belgium) for construction blocks. For the present study, a green concrete block was produced using SSS as OPC replacement. Today, SSS is considered as an hazardous waste, therefore stabilization is needed before its recycling as low-quality aggregate. Alternatively, SSS can be also chemically activated to produce a new binder for green concrete, hence foregoing the need of SSS stabilization. Therefore, the potential switch in the recycling of SSS, from low quality aggregates to green concrete, affects both the construction blocks and the low quality aggregates markets. In order to analyse the environmental consequences of these changes in both markets, a C-LCA was performed including all processes that are significantly affected by the changes, namely the production of traditional concrete, the production of natural/secondary low quality aggregates and their transports. In order to understand how mechanisms of revenue maximization and price equilibrium are affected by the changes, market information and economic models are also considered during the Life Cycle Inventory phase. Finally, the recycling of SSS as a binder for building materials will reduce the emission of CO_2 and NO_x , thanks to the avoided use of OPC. At the same time the change in the final use of SSS causes an increase use of natural aggregates for low value applications, unless alternatives from other by-products are considered. The C-LCA approach indicates that replacing a material by a more sustainable option does not lead necessarily to a better overall sustainability. Policy makers should therefore consider interactions between different markets when analysing the effectiveness of policy-support actions, like the increase of the tax on the CO_2 emissions or subsidies for the use of SSS as a binder.

TU244

LCA for supporting a sustainable transition towards circular economy

L. Rigamonti, Politecnico di Milano / Department of Civil and Environmental Engineering; A. Falbo, Politecnico di Milano; L. Zampori, European Commision DG Joint Research Centre / Institute of Environment and Sustainability; S. Sala, European Commission - Joint Research Centre / Sustainability Assessment unit

Circular economy is an economic model based on resource optimization while fostering of the use of waste as resource. Within more circular economies, resource are used efficiently within the life cycle of a products and the waste generated along the supply chains are minimized and used as much as possible, directly of after transformation, as input for other products and systems. Supporting circular economy means improving the analysis of resource flows within sectors and products, defining and implementing new ecodesign strategies, ensuring low-toxicity in products and waste, as well as fostering waste prevention and recovery. Moving toward more circular economy requires that different waste management options are systematically scrutinized to assess the environmental impacts and benefit associated to them. The present work aims at illustrating how a sensitivity analysis could be applied to the impact assessment step supporting the interpretation of a LCA study applied to a waste management system that includes material recovering. The focus is on toxicity-related and resource-related potential impacts as they are considered among the most critical ones, which may affect the way the final benefit from material recovery is evaluated. Possible alternatives in terms of impact assessment assumptions and modelling are tested by performing a sensitivity analysis on a case study on electric and electronic waste. For the toxicity-related impact categories, a sensitivity analysis is performed focusing on the role of metal toxicity and long term emissions in upstream processes. For resource related impact category, a sensitivity analysis has been performed adopting different sets of characterization factors based on existing models for minerals and metals as well as recently proposed sets accounting to critical raw materials. The application of LCA is crucial for assessing avoided impacts and uncovers potential impacts due to material recovery. However, contrasting results may stem from the application of different assumptions and models for characterization. A robust interpretation of the results should be based on systematic assessment of the differences highlighted by the sensitivity, as guidance for delving into further analysis of the drivers of impacts and / or to steer eco-innovation to reduce those impacts.

TU245

Life cycle assessment of co-digestion on a wastewater treatment plant

M. Seier, TU Darmstadt / Department for Material Flow Management and Resource Economy; L. Schebek, TU Darmstadt / Material Flow Management and Resource Economy; C. Schaum, R. Lutze, J. Rühl, P. Cornel, TU Darmstadt / Department for Wastewater Technology and Water Reuse

The increase of electricity self supply is a aim on municipal wastewater treatment plants (WWTP). A significant share of energy demands on WWTP is provided by biogas, generated by anaerobic digestion of sewage sludge. The biogas can be utilized in combined heat and power plants (CHP). Digestion of co-substrates is applied to increase the biogas yield and thereby energy self supply. However, an increased substrate input into the digester comes with an higher energy demand on the WWTP; moreover, an alternative usage of the co-substrate is hindered. Consequently, changing energy flows within the system have to be assessed. For assessing the trade-offs between an increase of energy self supply on the WWTP and additional energy/substance demands as well as the competing use of food residues as a substrate for electricity generation and for fertiliser substitution, Life Cycle Assessment (LCA) is used. A parameterised LCA model is built to assess different quantities of food residues fed into the digestion process on the WWTP. The model allows assessing plant-internal changes of energy and material demands/flows depending on different feeding amounts of co-substrates and the consequences coming from the substituted alternative treatment of food residues. Data for material and energy demands for this case study comes from a WWTP with a population equivalent of 240,000 in Germany. In the analysed case study, an additional amount of co-substrate (food residues) of about 15 weight percent is necessary to provide energy self-sufficiency on the WWTP. Due to the high energy content and the fast degradability of the organic matter of food residues, the increase in electricity self supply on the WWTP overcompensates additional energy and working material demands for treatment. Considering an alternative treatment of food residues, the total system-wide environmental impacts mostly depend on the CHP efficiencies on the WWTP / alternative biogas plant. Electricity self sufficiency on WWTP can be achieved by feeding a relatively low amount of substrates with a high energy content and using energy on-site. Depending on efficiencies of the digestion and the CHP plant on the WWTP and the competing biogas plant, co-digestion is not necessarily environmentally beneficial from a life cycle perspective. It is therefore necessary to include different treatment options and process efficiencies to assess impacts across systems.

TU246

Plastic waste treatment strategy in Switzerland: LCA approach based on parameterisation for robust decision support

T. Kägi, F. Dinkel, N. Ferronato, Carbotech AG

In this study we looked at post consumer plastic waste treatment options such as material recycling (open loop and closed loop if feasible) and thermal utilisation (plastic is not allowed in landfills in Switzerland). This study aimed at the strategic question: How should plastic waste from households be collected and utilized in Switzerland to lower the environmental (and economic) impact? A more specific question was: Does it makes more sense to continue the separate collection of specific plastic products like PET bottles or is there a higher benefit collecting a larger amount of plastic by doing a mix plastic collection like in other European countries. The main focus was on creating an utmost parameterized model using the SimaPro software v8.02. The variation of parameters such as transportation, sorting efficiencies, recovery rates, material quality, efficiency of energy recovery in the municipal waste incineration, electricity and heat mix substitution allowed a holistic scenario analysis for optimisation potentials regarding collection processes, recycling processes and thermal utilisation processes. The findings of the model analysis showed that the existing separate PET-collection is meaningful but the present system could be improved by expanded separate-mixed collection like PE-bottles and beverage cartons or PE-bottles and films . The actual Swiss recycling system represents a scenario which is rated as average in a sense of functionality but it does still leave room for improvement compared to the best options resulting in reduction potentials of about 20 % in the next 15 years. Interestingly, the mixture of all plastics (mixed collection) performs worst mainly due to the negative influence to the material quality and sorting efficiency. In summary, an improved recycling system for the whole of Switzerland would be ecologically worthwhile and would allow an improvement and expansion in the plastic recycling system. The model proofed to be useful for evaluating different options regarding measures taken in the field of circular economy of plastics.

Methodological challenges for LCA of agricultural supply chains producing food, fibre and bioenergy (P)

TU247

Methodological challenges for LCA of agricultural supply chains producing food, fibre and bioenergy (poster)

A. Avadí, INRA-Agrocampus Ouest / UMR SAS

LCA theory and practice still feature a number of methodological challenges, some of which are not fully solved by the research community. When LCA is applied to agriculture (i.e. cradle to farm gate), as well as to agri-food, bioenergy and fibre systems (i.e. cradle to processing plant gate) and supply chains, specific challenges arise, regarding for instance, modelling of direct emissions, allocation strategies and their consequences, land use and land use change (LULUC) and their impacts on biodiversity and climate change, responsible sourcing of agricultural products, the role of LCA to assess production and utilisation of bioenergy; as well as the extrapolation of farm level assessment to describe agricultural regions. Among methodological challenges, models for direct emissions in particular have been continuously developed and expanded to address the transportation and fate of pesticides (see FATE track), LULUC, carbon sequestration, and specific soil and water emissions, among other topics. A key question regarding direct emission models would be whether a common methodological framework is possible and desirable. Regarding the use of LCA to compare competing agricultural strategies, including bioenergy and fibre production, both at the farm, regional and supply chain (i.e. beyond regional) levels; certain methodological challenges hinder the validity of these comparisons. This session intends to advance discussion on methodological challenges to agricultural LCA and its solutions, with emphasis on convergence of methods towards a common framework acceptable for both academia and industry. It will appeal to LCA practitioners studying agri-food, bioenergy and fibre-based systems and supply chains, but also to modellers dealing with agricultural systems at the field, farm and regional levels. The presentation of case studies is acceptable when it contributes to introduce methodological developments towards overcoming current (and future) challenges of LCA of agricultural systems and supply chains, including bioenergy production systems.

TU248

Challenges for improving iLUC negative effects of biofuel demand in Spain

J. Serrano-Sánchez, CIEMAT / Energy Dpt   Energy Systems Analysis Unit; D. Garrain, CIEMAT / Energy Energy Systems Analysis Unit; Y. Lechon, CIEMAT / Energy Dpt   Energy Systems Analysis Unit

From a consequential approach, biofuel life cycle greenhouse gases (GHG) analyses could present great differences if the effects of the indirect Land Use Changes (iLUC) are considered. These potential iLUC impacts relate to the unintended consequence of liberating more carbon emissions due to land-use changes around the world induced by the expansion of croplands for biofuel production in response to the increased global demand. The Energy Systems Analysis unit of CIEMAT has carried out some previous studies in order to analyse the iLUC effects, in terms of CO_2 emissions, of biofuel consumption in Spain. Results showed a great interval of variation of figures for the majority of biofuel types, especially in sunflower and rapeseed biodiesel, with average emissions ranging from 20 to 60 g CO_2 eq / MJ in biodiesel, and from 16 to 60 g CO_2 eq / MJ in bioethanol. The main reason for these large intervals was due to the selection of the location of raw materials. This study is divided in two parts. First part presents an analysis of the main economic and biophysical key factors for reducing negative effects from iLUC, such as the high dependency of the elasticity of prices, the choices of types and geographical location of crops, or the consequential use of coproducts from biofuel production. Finally, an example of the implementation of some of these measures in previous studies of iLUC effects of biofuel demand in Spain is presented.

TU249

Environmental Impact of Food Losses from Agriculture to Consumption in Switzerland

C.R. Beretta, Institute of Environmental Engineering ETH Zurich / IfU; C. Oberschelp, ETH Zurich; S. Hellweg, ETH Zurich / Institute of Environmental Engineering

Twenty to thirty percent of the environmental impact of consumption are caused by food consumption (Tukker et al., 2006). A key element to make our food system more efficient and sustainable is the reduction of food losses across the entire food value chain (Quested and Johnson, 2009). However, for the implementation of measures against food losses it is important to know which losses are environmentally most relevant. We quantified the amount of food losses at the various levels of the Swiss food value chain (agricultural production, postharvest handling and trade, processing, food service industry, retail, and households) in terms of mass and energy (Beretta et al., 2012). About one third of the food available for Swiss consumption (production and imports) is lost in terms of metabolisable energy. However, the environmental impact of food losses do not only depend on the amount of food loss, but also on the type of food, the degree of processing, the level in the food chain on which the losses occur, and the method of treatment (incineration, composting, anaerobic digestion, feeding). Therefore, we quantified the environmental impact of food losses at the various stages of the food value chain in Switzerland. Based on the mass and energy flow analysis, twenty-three food categories are modelled separately, representing the whole food basket. For the impact assessment the categories climate change, ecological scarcity 2013, water, and land use are considered. The results show that the food losses at the end of the food value chain cause the highest environmental impacts. Firstly, they are quantitatively relevant, representing roughly half of the overall food losses; and secondly, they cause higher impacts per kg of product because of the accumulation of the impacts of the previous stages of the food chain. The net environmental credits from the treatment of food losses are between 5 and 10% of the impacts of the supply chain allocated to the losses. Therefore, avoiding food waste is much more effective than optimizing the method of treatment. About half of the environmental impacts from total avoidable food losses can potentially be avoided by solely addressing households. Furthermore, the highest environmental benefits from avoiding one kg of food loss of average composition can be achieved in households and food service institutions. This can help public and private decision makers prioritize their strategies for preventing food losses.

TU250

Country-based and spatially-explicit Land Use Change matrix

M. De Rosa, Arhus University / Agroecology; M. Vestergaard Odgaard, Department of Agroecology Aarhus University

LCA of bio-based products present some specific methodological challenges. Among those, modelling Land Use and Land Use Changes (LULUC) and forestry (LULUCF) has proven particularly controversial. Despite recent developments, neither remote sensing nor country-based land use statistics can alone provide spatially-explicit information on LULUC by land category. Satellite images cannot always distinguish between managed and unmanaged land (e.g. forest) and shows limits in determining percent tree cover for low cover density; national statistics present limitation in terms of data quality and consistency between countries. In order to overcome these limitations, we combined the strengths of the state-of the-art remote sensing land cover datasets *Collection 5 MODIS Land Cover Type* and the *FAOSTAT* and *Forest Resources Assessment* (FRA) *2015* statistical databases. The aim was to obtain a country-based land use change matrix, as suggested by the IPCC Good Practices Guidance for LULUCF, where the area undergoing a transition between all possible land use categories between two reference years is represented by grid cells geographically identified.\n\nThe outcome was the first country-based consistent set of spatially-explicit LUC matrices. The matrices allow advanced LUC analyses aiming at: identifying: where natural land is converted and into what land type; where is cropland expanding and where is decreasing; identify land not in use or unproductive arable land; the location and therefore the potential productivity of land in transmission etc. Four versions of the matrix were generated per country, representing different levels of land-use-categories aggregation, suitable for different type of analysis. Country LUC matrices were also generated for three reference years: 2001-2012, 2005-2010 and 2010-2012 based on consistent available data and a draft version for 2010-2015. \n\nThis study represents the first attempt to consistently generate top-down LUC matrices for all countries. The matrices identify the area undergoing a transition between all possible land-use categories represented for two reference years. The methodology generating the LUC matrices used existing available data to obtain a spatially-explicit representation of land transformation. These LUC matrices intend to be a starting point for further country-specific detailed analyses, based on on-site data sampling.

TU251

Modelling the environmental effects of selected agricultural management strategies with regional statistically-based LCA

A. Avadí, INRA-Agrocampus Ouest / UMR SAS; M. Corson, INRA, UMR SAS; H. van der Werf, INRA, UMR SAS / Environnement etAgronomie

Despite the farm being considered by many as the most suitable level of decision making and strategic management in agriculture, there is an increasing interest in evaluating agricultural management strategies at the regional level. Recent initiatives attempted to aggregate and generalise farm-level life cycle inventory (LCI) data and life cycle impact assessment (LCIA) results to describe the environmental performance of agricultural regions. We propose a regional statistics-based approach for constructing virtual representative farms (VRFs), representing dominant farm types for a given region, as a tool for comparing alternative regional agricultural strategies in contexts of insufficient farm (e.g. LCI) data. The proposed method has been applied to the agricultural Brittany region, in France. The environmental impacts of different agricultural management strategies were estimated at the regional level, by modelling the strategies as changes in VRF-based LCIs, calculating LCIAs, and extrapolating their means to the total land use in the region. Based on this assessment, performed using a regional life cycle assessment (LCA) framework, we have analysed the relative environmental impacts of each management strategy on the region. By adding a concise qualitative economic assessment, a strategy comparison matrix was built to allow farmers and other decision makers to understand the implications of implementing each strategy. The method aims to approximate regional environmental impacts from agriculture, including farm-level changes in management practices propagated to the regional scale. This work is currently under development.

TU252

Combining Life Cycle Assessment and economic modelling to assess effects of agricultural policies on the environmental impacts of the French dairy sector

T. SALOU, INRA, UMR SAS / UMR SAS UMR SMART; C. Le Mouël, F. Levert, A. Forslund, J. Hercule, INRA Agrocampus Ouest / UMR SMART; H. van der Werf, INRA, UMR SAS / Environnement etAgronomie

European dairy production is facing great changes. Removal of milk quotas, increased farm size and increased demand for dairy products are the drivers for these changes that are expected to affect the volume of raw milk produced, the structure of the milk production sector and the environmental impacts of the milk produced. Following the Common Agricultural Policy Health Check in 2008, impacts of quotas removal on prices and milk supply in the European Union (EU) and/or its Members States (MS) have been widely studied. However, supply and environmental impacts of this policy change through its effects on milk production systems and their share in EU and/or MS milk production, have been less studied, and, to our knowledge, never through a Consequential Life Cycle Assessment (CLCA) approach. We combined LCA and economic modelling to assess environmental impacts of public policies in the French dairy sector through CLCA. MATSIM-LUCA, a partial equilibrium model, was used to project agricultural markets to 2030, based on OECD forecasts. Several scenarios, representing different policy and food demand contexts, were simulated: i) SRef, which is the baseline scenario, representing the agricultural markets in 2030; ii) $SRef_0$, representing the agricultural markets in 2030 if dairy quotas had still been in force; iii) $S1_{LD}$, corresponding to SRef with reduced growth of world demand for milk as compared to OECD forecasts; iv) $S1_{HD}$, where SRef is implemented with increased growth of world demand. For each scenario, MATSIM-LUCA gives results, for the various regions considered (including France and EU) for: i) the share of dairy production systems; ii) the quantity of milk produced, consumed and traded, the prices for milk and agricultural goods; iii) the areas for crop and grasslands. These outputs are used to feed a LCA model. CLCA, through scenario comparison, is then performed. A range of impacts are examined, including land use change and intensification of crop production.

TU253

Developing a data-driven model to quantify farm-specific greenhouse gas life cycle emissions for open-field tomato production on a global scale

W. Lam, Department of Environmental Science; M. Kulak, I. Butnar, Unilever RD Colworth / Safety and Environmental Assurance Centre SEAC; S. Sim, Unilever R&D / Safety and Environmental Assurance Centre; M. Douziech, Radboud University Nijmegen / Institute for Water and Wetland Research; R. Van Zelm, Radboud University / Department of Environmental Science; M. Huijbregts, Radboud University Nijmegen / Department of Environmental Science

Greenhouse gas life cycle (GHG-LC) emissions from crop cultivation consist of biogenic carbon emissions from land use change, nitrous oxide (N_2O) emissions from fertilizer application and fossil emissions due to use of machinery and material inputs. Biogenic greenhouse gas emissions vary spatially as a consequence of variation in soil composition and phytomass organic carbon as well as differences in farm management practices and technologies (e.g. tillage). Furthermore, N_2O emissions are directly related to the amount of fertilizer applied. Variability in fossil emissions is primarily caused by technological differences across different farms in different regions while variability in yield is amongst others attributed to temporal climatic differences, e.g. temperature and rainfall. There has so far not been a study that considers spatial, technological and temporal variability of GHG-LC emissions of crop production at a high spatial resolution. The objective of this research is to construct a data-driven model to estimate farm-specific GHG-LC emissions per kg of tomato produced. For this, data of open-field tomato cultivation from multiple farmers were collected in 16 countries. Within each country, data were available for a number of farms for 1, 2 or 3 years. Data include, among others, locations of farms, local climate, farm yield, soil quality including soil organic matter, pesticide application, fertiliser input, energy consumption, and water consumption.

TU254

Water use as a regional LCA indicator in the production of bio-based succinic acid using corn and wheat as potential primary resources in France

S.A. Leal Meza, Universite de Technologie de Troyes / Hetic; J. Kim, University of Technology of Troyes / Department of Humanities Environment Information Technology CREIDD; N. Troussier, Universite de Technologie de Troyes / Hetic

Water availability and usage is of increasing concern in modern society (Vink & Davies, 2015). In LCA practice has been pointed out that water use is an indicator that should be assessed in the local or regional context, (Pfister, et al., 2009; Vink & Davies, 2015; others) so the use of regional data is more relevant to obtain more reliable values for this indicator. Bioeconomy is currently targeted as a strategic axis in the European Commission country members, in France particularly, it is expected to support the depletion of non-renewable resources and it is aimed to achieve a sustainable production model of biomass sources (Colloque Bioeconomie France, 2015). Bioeconomy growth could imply putting more pressure on water availability, depending on local conditions, thus it is important to review the increasing biomass uses regarding its implicit water use as an LCA indicator at regional level. As part of the bioeconomy, several biobased chemicals like biopolymers or chemical building blocks are increasing and they are expected to increase their production (NNFCC, 2015). The present work aims to contribute on sharing the experience to calculate water use as an LCA indicator, using regional inventory data for the production of wheat and corn in the regions Picardie and Alsace in France, assuming that these crops are the primary raw materials for succinic acid production in the country. Regional Life Cycle Inventories for crop production were obtained through an organization having access to specific data in the selected regions. Intermediate life stage inventories were obtained from literature, as well as from Agribalyse French database as a third inventory source for crop production, to observe differences when using average national data. Methodologies used to estimate water use are ReciPe 2008 and ILCD with adaptations to include water scarcity factors (as presented by A.M. Boulay et al., 2011). Discussion and results cover the life cycle water use in the set scenarios, and the methodological issues to estimate the LCA indicator.

TU255

The challenge of combined assessment of environmental impact and supply of essential fatty acids in omnivore and vegetarian diets

C.R. Coelho; F. Pernollet, INRA Agrocampus Ouest; H. van der Werf, INRA, UMR SAS / Environnement etAgronomie

The relationship between food and environment has been gaining attention in recent years, as a consequence, some life cycle assessment studies have taken into account not only energy or protein intake but also more sophisticated nutritional quality indicators. We used LCA methodology to assess four contrasting diets consisting of foods usually consumed in France. We investigated an Average diet, a Healthy diet, a Healthy diet without fish and a Healthy vegetarian diet, where the Healthy diets correspond to recommendations regarding macronutrients in France. Research has shown that increasing omega-3 fatty acid content of animal feed may result in higher omega-3 fatty acid content of animal products. Several non-fish products with higher omega-3 levels are available in the market in France. For each of the four diets we investigated the environmental impacts of the substitution of standard animal products (milk and beef, sheep milk, goat milk, rabbit meat, chicken, egg and pork), wheat flour and oil by the corresponding omega-3 enriched food items. To assess the environmental impacts the following impact categories were used: global warming (GWP) acidification (AC), eutrophication (EU), land occupation (LO), cumulative energy demand (CED) and biotic natural resources depletion-species (BNR-eco). Moving from Standard to increased omega-3 versions of the four diets improved nutritional quality without increasing environmental impacts. Shifting from Average diet to Healthy diet improved nutritional quality and decreased environmental impacts by 10 to 30 % depending on the impact. Shifting from Average to Vegetarian diet reduced environmental impacts by 11% to 49%, but decreased nutritional quality in terms of omega-3 contents. These results highlight the challenges of carrying out LCA studies of diets and stress the importance of the inclusion of nutritional quality indicators which go beyond kcal intake or macronutrient ratios. This work was supported by the French AGRALID project (ANR-12-ALID-0003)

TU256

Impacts of food consumption: a missing hot spot in LCA?

A. Ernstoff, Quantitative Sustainability Assessment; O. Jolliet, University of Michigan; K. Stylianou, University of Michigan - School of Public Health / Environmental Health Sciences; P. Fantke, Technical University of Denmark / Quantitative Sustainability Assessment Division

Use stage (i.e. food consumption) impacts are inconsistently accounted for within LCA and likely constitute a hot spot of considerable magnitude with respect to human health impacts of food systems. As case study examples, methods are lacking to assess global and regional nutritional impacts and to account for exposure to chemicals within food contact materials (e.g. packaging). This study's objectives are to develop methodologies to address *consumption* of food products and associated impacts as a potential hot spot within LCA. We extend life cycle thinking (LCT) to a broader disciplinary context to raise awareness in the LCA community about global and regional public health "hot spots", e.g. identified through epidemiology. Data is collected to build an inventory of chemicals within food packaging materials, and we estimated and characterized exposure, and identified major research gaps and areas of prioritisation. Also to investigate consumption as a potential hot spot, regional and global epidemiology-based models were developed to estimate disability adjusted life years (DALYs) associated with various dietary unit-mass intakes (e.g. gram of sodium). Applying life cycle thinking (LCT) and a broader disciplinary context can help redirect environmental sustainability assessments towards priority regional and global human health issues specifically with respect to food systems.

TU257

Joint assessment of environmental Life Cycle Assessment results and grape quality using multicriteria evaluation with fuzzy logic

S. Beauchet; R. Botreau, INRA, UMR1213 Herbivores; C. Bockstaller, INRA, UMR1121 Agronomie et Environnement, Inra-Université de Lorraine; C. Renaud-Gentié, Ecole Supérieure dAgricultures; M. Thiollet-Scholtus, INRA SAD / URASTER; F. Jourjon, Ecole Supérieure dAgricultures

Life Cycle Assessment (LCA) addresses different environmental impacts so that it provides a set of indicators results that can be contradictory. Deciding as well as comparing systems on more than one criteria becomes rapidely an impossible task. This becomes even more complicated when the number of indicators is increased by broadening the assessement to other issue like product quality.The objective of this work is to agregate a large number of LCA results which could be compared with the product quality assessment of a vine plot. LCA results can be aggregated by means of a tool called CONTRA (TRAnsparent CONstruction of decision trees). CONTRA is a method using fuzzy inference system to avoid threshold effects in aggregation. This tool aggregate several indicators into a single quantitative score. The advantage of such a method, when applied to LCA, is thus to study the LCA of a system through a single result in order to compare it to a single score obtained in the same way from product quality assessment. The comparison of environmental and quality issues is then simplified to the comparison of two scores. The first step consisted in defining with experts the decision tree: selection of criteria and their organization. Then, the evaluation model was constructed by defining the CONTRA parameters according to experts' opinion: definition of threshold values for each criteria, criteria weighting, and generic rules for the management of compensations between criteria. LCA's threshold values were defined by taking the extreme values obtained on a population of 5 vineyards, chosen to represent the diversity of viticultural practices for middle of Loire valley dry white wine grapes (France). Decision rules for compensations were decided to limit the compensation of a bad score on one criterium by a good one on another variable. CONTRA parameters that best correspond to these rules were then defined. The aggregation of results using CONTRA allowed an overall view of the LCA results of a system by producing a single synthetic score. Furthermore, CONTRA makes possible the analyze of the results more thoroughly backing up to the individual results and of environmental impacts and quality criteria, to identify elements to be improved and those to be maintained. Within this study, the use of CONTRA eased the comparison of environmental LCA results with another sustainability dimension, here the quality of the product.

TU258

Grape LCA : How to better assess organic and integrated technical management routes ?

A. Rouault, Ecole Supérieure dAgricultures; S. Beauchet; C. Renaud-Gentié, F. Jourjon, Ecole Supérieure dAgricultures

There is an increasing demand from society for informations on environmental impacts of products. In viticulture, there are a lot of different practices and there is a need for tools and methods that can give relevant informations on environmental impacts of these practices. Life Cycle Assessment (LCA) has been recently identified as a useful tool to develop more sustainable agricultural systems and as a relevant method to assess environemental impacts of agriculture on a plot scale. A method has been proposed by Renaud-Gentié et al. to assess environmental impacts of technical management routes (TMR) on a plot scale based on LCA. This study apply this methodology on two case studies and goes through methodological improvements needed for a better assessment of organic and integrated viticulture practices. Results show that the studied organic TMR has significantly more impacts on global warming potential, photochemical ozone formation potential and acidification potential. Concerning freshwater ecotoxicity potential and resource depletion, impact score difference between organic and integrated TMR is very small. The case study shows how current application of LCA methodology to viticulture is not sufficient to assess different types of viticulture. In this methodology, several major issues are not assessed fairly or not assessed at all. For example, adding a soil quality indicator among impact categories seems important as maintaining initial soil properties is a key issue for agriculture sustainability. Carbon sequestration in the soil is another important issue which is not taken into account in Grape LCA whereas existing good techniques in this field may be promoted by LCA. Concerning ecotoxicity, modelling of emissions to soil, water and air from copper and sulfur-based products (mainly used in organic agrilculture for pest management) doesn't exist. Finally, data used for fuel consumption of machinery are not totally satisfactory and can also be improved.

TU259

A new biophysical allocation in LCA of beef cattle coproducts: modelling energy requirements of body-tissues growth

A. Wilfart, INRA, Agrocampus Ouest / UMR SAS; X. CHEN, INRA, UMR SAS

/ UMR SAS; L. Puillet, INRA, AgroParisTech, Université Paris-Saclay / UMR MSAR; J. Aubin, INRA , Agrocampus Ouest / UMR SAS

In agricultural life cycle assessment (LCA), the choice of allocation methods to spread out impacts between coproducts is an important issue, as they may induce different conclusions in impact levels. We proposed a biophysical allocation method to dispatch the upstream environmental burdens and the use of raw materials to the body-related coproducts of beef cattle production system at slaughterhouse stage. The method is designed to build a relationship between coproducts of the beef cattle production system and their associated net energy requirements for body growth. So it doesn't take into account the fate of the different coproducts, but only their building costs (i.e., energy needed for building tissues). A combination of metabolic growth model (Gompertz function) and energy model was used to estimate the energy requirements for body growth from birth to slaughter age. The allocation factors were calculated based on the energy requirements attributed to build body tissues characterized by their chemical compositions (protein and lipid) and. Finally, this method was compared with other allocation methods (e.g., physical, economic). The biophysical allocation reflects a physical and biological relationship between the coproducts as required by ISO standard. It provided a moderate allocation factor for human food due to their chemical characteristics compared to the other physical allocation methods. In addition, the data required is specific to species and less influenced within a predefined system than economic allocation. This study provides a generic and robust biophysical allocation method to handle the coproducts in beef cattle system. The method can be considered as an original contribution to the international debates on the allocation methods in LCA applied to livestock products, especially among the stakeholders of the meat value chains.

TU260

How to take into account the crop rotation into Life Cycle Assessment of crop at national scale ? Methodological development and results from ECOALIM project

A. Tailleur, ARVALIS - Institut du végétal; S. Dauguet, Terres Inovia; A. Wilfart, INRA Institut National de la Recherche Agronomique / UMR SAS; S. Willmann, ARVALIS - Institut du végétal; M. Laustriat, Terres Inovia; h. HEITZ, ARVALIS INSTITUT DU VEGETAL; S. Espagnol, IFIP

Animals' feeding contribute very significantly to the overall environmental impact of animal products. The French project ECOALIM aims to improve the environmental impacts of husbandries by optimizing their feed. This project (1) defines the environmental impacts of the production of raw materials for animal feeding basing on Life Cycle Assessment (LCA) and (2) optimizes the formulation of compound feed with environmental constraints in order to improve environmental footprint of animal products. Animal feeding optimizing could induce substitution from one crop product to another into the formulation. In the meantime, it is difficult to allocate the impacts of a production system to each crop in a crop rotation because emissions depend on practices implemented on the whole crop rotation and not only a single crop. The method to allocate emissions between crops and its results on 12 case studies are discussed here. Specific methodological developments were made in particular to allocate nitrate (NO_3^-) and phosphorus (P) losses between crops. NO_3^- leaching due to the nitrogen (N) fertilization of one crop depends on the applied quantity but also on the intercrop management and on the following crop. As P is immobile in the soil, some farmers use residual nutrients by applying P fertilizers to one crop only in quantities sufficient to supply the off take and needs of following crops. Hence, after assessment of different allocation rules, NO_3^- was allocated equally between crops within a same rotation and a specific rule was defined to allocate P in function of off take and needs. Organic N was allocated according to the rule used for Agribalyse. For each case study, LCA was applied on a basic scenario and on 3 crop management scenarios, aiming to reduce environmental impacts related to loss of nutrients and use of mineral fertilizer: 1) introduction of intermediate crops, 2) introduction of legumes in the rotation, or (3) organic fertilization (with 2 options for the choosen organic fertilizers in each case study, 3-1 and 3-2). LCA results show that if these rules seem pertinent to allocate benefits of some crop management between crops, they raise questions for some others (cf table 1). Finally, these results represent a step forward in order to take into account system production improvements in LCA of single crop but also show that some developments are still required as results obtained with a same method are very variable in function of hypothesis.

TU261

Biomarker analysis in soils of the Amazon rainforest after vegetation fire

J.B. da Costa, UFRGS / Analytical Chemistry; D.P. Dick, Federal University of Rio Grande do Sul / Physical Chemistry; M.O. Lima, L.Z. Lara, M.R. Peralba, Universidade Federal do Rio Grande do Sul; F.d. Costa, Embrapa Acre

Biomarkers, also known as molecular markers, refer to compounds that have a relationship with their precursors and indicate the occurrence of a particular process within an organism. Recently, the evaluation of biomarkers in plants or soil has become a more common procedure, since the abundance of these compounds are sensitive to changes in the soil organic matter (SOM) caused by the use and management of soil. The content of this fraction comprises much of the soil aliphatic structures and may give information about the source of the organic matter present in soil (microbial origin or higher plants) and is therefore called biomarkers. Studies on soils biomarkers can contribute to the understanding of the dynamics and stabilization of organic matter, which is of great importance from an environmental point of view.The objective of this study was to determine the origin of organic matter incorporated in Amazon forest soils subjected to vegetation fire by analyzing the aliphatic biomarkers (*n*-alkanes) present in lipid extracts of soil samples. The study area is located at Embrapa-Acre in Rio Branco, Acre/Brazil and consists of primary forest which was partially burned in 2011. Samplings were conducted in September 2012 (one year after burning) and September 2014 (three years after burning) in primary forest areas (PF) and burnt forest (BF) at two depths: 0-5 and 100-150 cm. Approximately 4 g of sample was used for lipids extraction. The samples were extracted via soxhlet with dichloromethane/methanol (3:1 v/v) for 24 hours. Completed the extraction step, the lipid extract was concentrated in rotary evaporator. The extracts containing lipids were then subjected to fractionation using preparative liquid chromatography atmospheric pressure. The distribution of *n*-alkanes was determined by GC/MS. The SOM of the primary forest comprises contributions of microbial moieties and of higher plants along the whole profile. This similar distribution pattern of *n*-alkanes indicates that a percolation of SOM fragments produced at the surface to the deeper layers occurred. After vegetation burning, a lipids fraction original from higher plants are fragmented in smaller chains, enriching thus the proportion of C₁₆ to C₂₄*n*-alkanes. This effect was also observed at the deeper layer, suggesting that the percolation of SOM along the profile is a constant and intense profile.

TU262

Life cycle assessment of hemp concrete blocs

S. Groslambert, University of Liège - Chemical Engineering / Dpt of Chemical Engineering PEPs; A. LEONARD, University of Liege / Dpt of Chemical Engineering PEPs

Buildings notably contribute to global environmental negative impacts due to consumption of both embodied energy and natural resources as well as various emissions during their whole life cycle. It is therefore necessary to develop practices to reduce these impacts, mainly by reducing the part of non-renewable resource in material as well as by ensuring the lowest energy consumption possible during their lifetime. New developments in natural fibres and their use in insulating materials can lead to significant improvement in building environmental impact. For this purpose, assessment of environmental performance is needed to support both the design and the production of (new) fibre based insulation solutions. In this context, the Life Cycle in Practice (LCiP) project helps SMEs to reduce the environmental impacts of their products and services across the entire life cycle. Within the frame of this project, Isohemp (BE) hemp concrete bloc impact is evaluated in a cradle-to-gate LCA. Functional unit is a pallet of hemp concrete blocs ready for shipping. It represents about 1.3 m^3 of blocs. Hemp blocs are made by pressing a mix of hemp shives, hydraulic and hydrated limes, and water. Long term carbon storage due to lime carbonation induces a large benefit in Climate Change (CC) category. The balance of the CC indicator for hemp cultivation is also favorable due to carbon dioxide uptake by the photosynthesis occurring during the plant growth. Life Cycle Assessment of hemp concrete blocs ready to ship has also highlights some improvements that can easily be made at the packaging level in order to lower the global environmental impact and increase the sustainability of this insulation material. Data are processed in SimaPro 8 software, with Ecoinvent 3 and ELCD 3 databases, and analyzed with the CML IA method. This method is compliant with the indicators required by EN15804 standard in order to communicate on the environmental performance of Isohemp blocs.

A regionalised life-cycle analysis structure for sustainability assessment of bioenergy systems

A. Ajayebi, University of Exeter / Renewable Energy; P. Connor, T. Taylor, X. Yan, University of Exeter

sustainability assessment of bioenergy systems is often challenged by various uncertainties including spatial variables. Life-cycle assessment (LCA) is a reliable methodology for sustainability assessment and it has been applied extensively to bioenergy and agricultural systems. The step-by-step structure of LCA is capable of taking into account environmental repercussions of the whole life cycle of bioenergy production, but the results are often only valid for specific case studies or too general to be used for regional decision making. By enhancing the generic structure of LCA and expanding the current datasets, we are proposing a more efficient procedure which is capable of producing region-specific results. The suggested framework includes techniques for making the life cycle inventories more relevant by regionalised compilation procedures. In addition, the framework integrates improved selection of appropriate impact assessment models. This methodology can specifically be used by local stakeholders or decision makers, who are considering producing energy biomass, as a guide for improving the environmental performance and efficiency of their activities.

TU264
Influence of crop management on water use of agricultural products. Case study: soybeans (Glycine max) in conventional tillage versus no-tillage in Argentina
R. Piastrellini; A. Arena, B. Civit, Universidad Tecnológica Nacional. Consejo Nacional de Investigaciones Científicas y Tecnológicas
The aim of this study is to analyze the influence of tillage systems in assessing consumptive use of water in agricultural products. A new procedure which allows the incorporation of the water balance of the soil on the green and blue water footprints calculation is presented. For this, an adjustment of crop evapotranspiration and surface runoff is performed, taking into account the effects related to the presence of stubble, crop cover and surface roughness. The case study of soybean (Glycine max) in conventional tillage and no-tillage in Argentina constitutes the first application of this procedure. The results confirm that no-tillage reduces soil evaporation, prolongs the water storage period in the soil, delays the onset of the surface runoff and decreases runoff depth. This improves the water availability to satisfy crop needs and therefore increases the consumption of green water. The increased water availability increases the crop productivity, resulting in a diminution of green water footprint. If the soybean is grown under irrigation, the increase on the green water consumption corresponds to blue water savings. The considerations of tillage systems in assessing green and blue water footprints would be highly relevant in products derived from crops whose productivity is evenly influenced by hydric stress throughout the growing cycle. Likewise, tillage effects on the green and blue water footprints would be of greater magnitude for crops grown in regions with regular rainfall, or where the periods of greatest rainfall take place during the stage of crop development.

TU265
Modelling agricultural production: systematic analysis of secondary Life Cycle Inventories
S. Corrado, Universita Cattolica / Institute of Agricultural and Environmental Chemistry; V. Castellani, European. Commission - Joint Research Centre / Institute for Environment and Sustainability; L. Zampori, European Commision DG Joint Research Centre / Institute of Environment and Sustainability; S. Sala, European Commission - Joint Research Centre / Sustainability Assessment unit
The analysis of agricultural production with life cycle based methodologies is very data demanding. In order to build comprehensive life cycle inventories, the use of secondary datasets is a common practice when primary data are not available. However, different inventory data and modelling approaches are used to populate secondary datasets, leading to different results. This can limit the perception of the reliability of the LCA tool especially when it is used for comparison purposes, e.g. among different food products and competing agricultural practices. We analysed the features of secondary datasets for agricultural production with the aim to identify how different inventory data and modelling choices can influence the LCA results. The outcomes of the analysis can support LCA practitioners in the selection of secondary datasets and proper interpretation of the results and can contribute to the challenge of defining a common modelling framework for agricultural production. Wheat grains production in France was assessed using three datasets from different databases (Agrifootprint v1.0, Ecoinvent v3.1 and Agribalyse v1.2). Firstly, we compared the system boundaries and the general assumptions. Secondly, we focused on the foreground systems by comparing inventory data, data sources and modelling approaches. Thirdly, we performed a contribution analysis on the impact assessment results to identify those modelling choices that contribute the most to differences in the results. We identified and assessed nine relevant elements: definition of system boundaries and modelling of agricultural practices; characteristics of inventory data; agricultural operations modelling; fertilisers' application and fate; plant protection products application and fate; heavy metals inputs to the agricultural system and fate; irrigation assumptions; land use and transformation. These elements included crop-specific data, such as the amount of inputs provided to the field, and database-specific modelling approaches, common to all the datasets modelling agricultural production within the database. The three datasets differed greatly with respect to those elements. Hence, we drew recommendations from the analysis of database-specific modelling approaches, supporting LCA practitioners in the selection of the datasets coherently with the goal and scope of their study and in the interpretation of the results and fostering the development of common rules to model agricultural production.

Ecotoxicological assessment and water quality monitoring in support of marine and freshwater legislation in Europe (P)

TU266
PAH exposure, genotoxicity and histopathological alterations in Scottish flatfish
K. White, C.D. Robinson, Marine Scotland Science; C. Stenton, Cefas; F. Gunn Folmer, M. Marcos Lopez, Marine Scotland Science
The UK has long been committed to monitoring and assessing the quality of the marine environment, and has a vision for its seas to be Clean, Safe, Healthy, Biologically Diverse, and Productive. Along with other countries, the UK reports marine monitoring data to international bodies such as the International Council for the Exploration of the Sea (ICES) and the OSPAR Convention for the Protection of the NE Atlantic which will be used in assessments under the EU Marine Strategy Framework Directive. As part of the Scottish monitoring programme flatfish blood samples were collected from the Firth of Forth, Moray Firth, offshore Scottish east coast and the North Minch. Samples were assessed for the presence of micronuclei, nuclear buds and binucleated erythrocytes and the results compared to observed liver histopathologies and exposure to polycyclic aromatic hydrocarbons, as indicated by biliary 1-hydroxypyrene concentrations; the significance of the data was assessed using OSPAR Assessment Criteria. The differences between polluted sites and 'cleaner' offshore site were examined, alongside differences between European plaice (*Pleuronectes platessa*) and common dab (*Limanda limanda)*. The highest biliary PAH concentrations and greatest frequency of micronucleated erythrocytes were observed in flounder from the industrialised lower Forth estuary; early toxicopathic lesions and foci of cellular alterations were also more commonly observed in fish from the Forth. PAH exposure and toxicological responses were lower in offshore dab, particularly those from the North Minch (NW Scotland).

TU267
ANALYSIS OF COMMUNITY-LEVEL MESOCOSM DATA BASED ON ECOLOGICALLY MEANINGFUL DISSIMILARITY MEASURES AND DATA TRANSFORMATIONS
C. Tebby, INERIS / METO; S. JOACHIM, INERIS / CIVS; P. van den Brink, Alterra and Wageningen University / Aquatic Ecology and Water Quality Management Group; J. Porcher, INERIS / INERIS UMRI SEBIO ECOT; S. ANDRES, INERIS / Toxicological Ecotoxicological Assessment of chemical Substances; R. Beaudouin, INERIS / Models for Ecotoxicology and Toxicology METO
The Principal Response Curves (PRC) method is a constrained ordination method developed specifically for the analysis of community data collected in mesocosm experiments which provides user-friendly summaries and graphical representations of the data. The PRC method is based on redundancy analysis (RDA) usually performed on log-transformed abundance data. The log-transformation is used to lower the weight of the most abundant species in the analysis and implies that the variations in abundance are scaled to the total abundance of each species. Many different measures to calculate dissimilarity between samples on the basis of the abundance of each species have been developed, in particular in the field of ecology. The measure of dissimilarity between samples and the data transformations have a very large impact on the results of the multivariate analysis. The Euclidean distance between samples is implicitly used in PRC, but in the field of ecology, many more dissimilarity measures are currently used. Distance-based redundancy analysis provides a basis for integrating more ecological meaningful distance measures into the PRC than Euclidean distance alone. In this paper, we investigated the ordinations produced with a small selection of ecological meaningful dissimilarity measures, namely the Euclidean distance on log-transformed data, the Hellinger distance, and the Bray-Curtis dissimilarity on raw and log-transformed data. We compared unconstrainted ordination as well as PRC results obtained with these dissimilarity measures for two different macro-invertebrate community datasets, resulting from experiments performed with anti-inflammatory drug diclofenac and the insecticide chlorpyrifos. In both cases, the ordinations obtained with unconstrained ordinations and RDA were similar, indicating that, once time effects had been partialled out, the treatment effects were the major source of variability in the data. In the diclofenac dataset, the Hellinger distance produced interesting significant results that completed those obtained with the Euclidean distance on log-transformed data. The chlorpyrifos dataset showed similar results for the different dissimilarity measures, with slight differences in the number of significant dates. The fraction of the total variance belonging to between-replicate and time-dependent variation appeared to be an important criterion in the selection of a dissimilarity measure.

TU268
A complete pesticide monitoring in small Swiss rivers over a growing season applying a screening method and a continuous sampling strategy
R. Comte, Eawag, Aquatic Research / Uchem; S. Mangold, H. Singer, C. Stamm, T. Doppler, Eawag Swiss federal Institute of Aquatic Science and Technology / Uchem; C. Moschet, UC Davis / Civil and Environmental Engineering; I. Wittmer, Eawag Swiss federal Institute of Aquatic Science and Technology / Uchem; M. Kunz, Federal Office for the Environment FOEN
Agricultural pesticides are regularly found in surface waters at concentration levels that raise ecotoxicological concerns. Due to large fluctuations in concentration over time and the potentially high number of pesticides in agricultural watersheds, it is difficult to obtain a comprehensive overview of the actual pollution level. This collaborative project between research and Swiss federal and cantonal authorities aimed for a comprehensive analysis of pesticide pollution in five small agricultural streams to address this knowledge gap. The five rivers are located in catchments with intensive agriculture covering a wide range of crops, such as grains, vegetables, vineyards and orchards. Twelve-hour composite samples were collected continuously from March until the end of

August with automatic sampling devices, resulting in 360 samples per site. Using precipitation and water level data, we differentiated between discharge events and low-flow periods. Samples taken in dry weather between rain events were pooled for the analysis. This procedure resulted in a complete concentration profile over the entire monitoring period covered by 60 samples per site. The analysis, using liquid chromatography coupled to high resolution mass spectrometry (Orbitrap technology), involved a target screening of 248 pesticides including fungicides, herbicides, insecticides, as well as important transformation products. Data on the total number and distribution of pesticides, their detection frequency, crop specific applications and concentration time profiles will be presented. Preliminary results indicate substantial pesticide exposure since at least 20 different compounds were detected in each sample. One sample even contained a mixture of 80 pesticides. The majority of concentrations were in the low ng/L range but concentrations of a few compounds were very high (several micrograms/L) during discharge events as well as during low flow conditions and exceeded environmental quality standards (EQS).

Vulliet, Institut des Sciences Analytiques / UMR Equipe Traces rue de la Doua Villeurbanne France

Pharmaceuticals are widely found in the aquatic environment, essentially at trace levels, nevertheless long-term exposure can have negative effects on biotic communities due to their intrinsic biological activity. Diclofenac (DCF) is one of the most frequently detected human pharmaceuticals in water and it has lately been included on the “watch” list of the European Union. However little data is available on the detection of this substance and its transformation products in aquatic organisms. In this context, analytical methodologies based either on QuEChERS or on ASE extraction followed by LC-MS/MS analysis were developed to quantify traces of DCF along with nine of its biotic and abiotic transformation products in bivalve, fish, sediment and watercress collected from lotic mesocosm experiments. The analytical protocol was first independently optimized and validated for each matrix of interest: sticklebacks, zebra mussels, sediment and watercress. For the optimization steps, uncontaminated matrices, corresponding to the matrices introduced into the mesocosms before the contamination with DCF were used. Considering the great diversity of transformation products and metabolites, a focus was made in this study on chemically stable and commercially available substances. Next target compounds were measured in samples collected from 6-months mesocosm experiments where DCF was continuously introduced in triplicate channels at three concentrations (5; 0.5 and 0.05 μg/L) and three more channels without DCF were used as control ones. DCF was quantified in zebra mussels and sediment for both highest exposure conditions and in watercress solely for the highest concentration. In sticklebacks DCF resulting concentration was inferior to our quantification limits probably due to rapid depuration as fishes were collected one week after the end of experiments. Among the selected metabolites, 4’OH-DCF was the most often quantified : it was observed in sticklebacks, sediment and watercress for the highest exposure concentration. The metabolites DCF-lactam and 5-OH-DCF were also measured as well as the 2-indolone either in sediment, watercress or bivalves. In this presentation, the optimization of the extraction and clean-up steps will be described. The results of the quantification of DCF, along with nine of its degradation products and metabolites, in organisms and watercress collected from mesocosms will be presented.

Science Integrity and Publication Bias (P)

What if Science follows Policies? The case of advanced biofuels

L. Patouillard, CIRAIG - École Polytechnique de Montréal; B. Cheze, IFP Energies nouvelles / Economics and environmental evaluation department

This article presents the results of a literature review performs with a meta-regression analysis (*MRA*) that focuses on the estimates of advanced biofuel *GHG* emissions assessed with a Life Cycle Assessment (*LCA*) approach. 47 *LCA* studies are included in the database, providing *593* estimates. Each study estimate of the database is characterized by *i)* technical data/characteristics, *ii)* author's methodological choices and *iii)* typology of the study under consideration. 82% of these *GHG* emissions results from North American (*NA*) authors are compliant with their more restrictive *GHG* emissions minimum threshold whereas it is the case for only 59% from European (*EU*) authors. This systematic difference between *NA* and *EU* observations may come from the use of a different set of technical variables, for instance, but it may also reveal the existence of a potential publication bias in the literature. Then, we conducted a *MRA* in order to identify the key factors influencing the results. Among others, we set the geographical location of authors as well as some technical data (type of technology, mass yield, etc) as explanatory variables. Results show that the geographical location of authors always has an influence on the *LCA GHG* emissions what ever the sample considered and that *NA* observations are always lower than *EU*. Investigating more in-depth a potential bias linked with the geographical location of authors, the Funnel graphs reveal the existence of an asymmetrical publication bias (*PB*) of *NA vs. EU* studies. This *PB* is then statistically tested by proposing an adaptation of the Funnel Asymmetry Test (*FAT*) of Stanley (2005). This test reveals a systematic *PB* of *NA* studies to publish results under the minimum thresholds for life cycle *GHG* emission savings specified by the *RFS2*, which is not the case for *EU* Studies. This result is of primary importance as it highlights the influence of the design of some public policies on the very scientific research and/or publication process. Policy makers have to be aware of this potential bias when designing new policies. Our results indicates a hierarchy between advanced biofuels as mean values of their LCA GHG emission weighted by the influence of its main drivers range from 19.5 (BtL) to 60.0 (G3) gCO_2eq/MJ of biofuel. This range of values is lower than fossil reference (about 83.8 in gCO_2eq/MJ), but only G2 Ethanol and BtL do comply with the GHG emission reduction thresholds defined in the US and EU regulations.

TU271

(No-)Effects of Polyoxometalates Encapsulated in Silica Nanoparticles in the soil invertebrate Enchytraeus crypticus

R.C. Bicho, CESAM University of Aveiro / Biology CESAM; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; H.I. Nogueira, Universidade de Aveiro / Department of Quimica; M.J. Amorim, Universidade de Aveiro / Department of Biology and CESAM

Polyoxometalates (POMs) are metal-oxo clusters that have been investigated for several applications in material sciences, catalysis and biomedicine and have gained increasing interest in the field of nanotechnology as nanocarriers for drug delivery. Associated to the increasing applications there is the need for information regarding the effects on the environment of these compounds, which is completely absent in the literature. In the present study the effects of europium polyoxometalates encapsulated into silica nanoparticles (Eu-POM/SiO_2 NPs) were assessed on the soil representative *Enchytraeus crypticus*. The individual materials were also assessed (Eu-POMs and SiO_2 NPs). Toxicity was evaluated in various test media with increasing complexity: water, soil:water extracts and soil. Toxicity was only observed for Eu-POM/SiO_2 NPs and in the presence of soil components. Despite the fact that effects were observed for concentrations higher than current PECs (Predicted Environmental Concentration), attention should be given to the growing use of these compounds. The present study shows the importance of assessing effects in soil media, also compared to water. Moreover, results of ‘no effect’ are critically needed and often unpublished. The present contributes to the improvement of the OECD guidelines for safety of manufactured nanomaterials on environmental toxicity in the soil compartment.

TU272

The axe over the academic head: science integrity for ecotoxicology in a high-pressure, science communication era.

A. Ford, University of Portsmouth / Biological Sciences

In science, integrity is critical, not only for the individual scientist but for public and political confidence to drive progression in knowledge. Ecotoxicology has developed into a fashionable field which is governed by public and political awareness, scientific bias for ‘pet’ pollutants and to a certain degree, new technologies which can lead to over-emotive scaremongering. Coupled with a high pressure working environment to deliver both funding and high quality publications, this creates a perfect storm to erode away science integrity, enhance conscious and unconscious bias and cutting corners in experimentation. This has recently been highlighted in the requirement to test the 'repeatability' of experiments across a number of scientific, including medical fields. To succeed as a young and established scientist in today's world, one must be able to publish regularly in high grade publications and show consistent funding successes beyond normal scholarly activities. There is an argument that to get your science published it must deliver significant results with impact resulting in publication bias. The consequences for not achieving this for many is job loss or at best the 'perceived' downward trajectory of teaching and administration. This paper highlights personnel observations of key pressure points on scientists whereby these pressures to consciously or otherwise cut corners is a growing concern for our field. In addition, whilst the #scicomm era is an excellent advancement in delivering factual science and impact right to the door of appropriate stakeholders, it also has the potential to allow people to drive their own agendas and ultimately harm public perception in science. There is a requirement to re-establish scientific integrity back onto the syllabus in science education; encourage publication of negative results and reduce pressure on academics to deliver ‘fast science’.

Tendency towards higher complexity in environmental risk assessment of Plant Protection Products: to accept or to

avoid? (P)

TU273
Sequences of pesticide applications: Is the prospective RA representative for the agronomic reality?
E. Kohler, Agroscope Wädenswil / Institute for Plant Production Sciences Ecotoxicology; L. de Baan, Agroscope / Institute for Plant Production Sciences IPS; A. Aldrich, Research Station Agroscope ACW / Ecotoxicology; B. Fulda, Agroscope; O. Daniel, Agroscope / Institute for Plant Production Sciences IPS
The prospective ecotoxicological risk assessment (RA) conducted during the registration of plant protection products (PPP) is a complex procedure, based on tiered assessments of toxicity and exposure. The exposure profile is directly affected by the application pattern of the PPP by the farmer. Thus, in order to assess the ecotoxicological risks of PPP, information on the PPP application is needed. Application parameters, i.e. application rate, number of applications and interval between applications, have to be established by the regulatory authority for each registered indication, i.e. use of a PPP on a specific crop and pest. Application parameters are established based on the following criteria: ensuring effective treatment of pest and reducing resistance risk, while keeping the risk of humans and the environment in an acceptable range. In this study we investigated, whether the prospective environmental RA is in accordance with the agricultural practice. Since 2009, data for PPP use of approximately 300 farmers are recorded within the framework of agri-environmental monitoring (AEM) in Switzerland. Specific information per lot of land is being collected about the actual use of PPP, including application rates, treated crops and application times. Based on this data set we analysed the application of PPPs, considering application rates, number of application and intervals between applications. These data from the AEM were compared to the authorised uses of PPP. First results indicate a high variability in the analysed AEM application parameters. However, despite their heterogeneity, the AEM data seem to largely be in accordance with authorised uses, considering parameters set in the registration such as application rates, number of applications and intervals. A high complexity of a RA is only justified if it does reflect the reality better than a less complex RA. However, by stating the parameters along with the registration a higher transparency and reliability may be achieved. General questions as to whether further standardisation and stating of application parameters is necessary and feasible or how sequential PPP applications could be considered in the registration are discussed.

Chemical Transport via the Global Food System (P)

WE001
Development of a method to extract chemicals from food for toxicity testing
K. Multer; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis; P.A. Neale, F. Leusch, Griffith University Smart Water Research Centre
Many environmental chemicals are known to be present in or on food. In particular, low income countries can suffer from the application of mostly banned and toxic pesticides in agriculture, combined with misapplied usage, which can lead to high food contamination. Owing to potential human health concerns, residues in food are generally identified with targeted chemical analysis. There is increasing awareness of assessing the biological effects of contaminants present in food, but few studies have applied *in vitro* bioassays for monitoring food based chemicals. To overcome this problem, the present study focuses on the development of a simple extraction method for bioanalytical testing of chemicals in food. The bioassays were selected throughout the cellular toxicity pathway, including induction of xenobiotic metabolism and cytotoxicity. The Chemically Activated Fluorescence gene expression assay (AhR-CAFLUX) detects compounds activating the xenobiotic mechanism via activation of the arylhydrocarbon-receptor (AhR). While this assay is typically used to screen for dioxin-like compounds, a set of other compounds, such as polychlorinated biphenyls (PCBs) and some pesticides, are known to activate the AhR. To screen for non-specific acting toxicants, the bacterial luminescence toxicity screen (BLT) assay was applied. This assay reflects the response of all chemicals present in a sample, causing different damages on bacterial cell viability. Liquid-liquid extraction, which was selected due to reduced solvent demand and rapid sample treatment, was applied for a range of food types. Additionally, washing water was also screened for chemicals to assess food processing. Regarding extraction efficiency, the method seems to be more efficient for high watery samples (strawberries, tomatoes) instead of fatty (fish, meat) and high fiber (apples) samples. Hence, higher biological effects were obtained for watery samples in the studied assays, including response of the washing water. Future work should focus on method improvement of the liquid-liquid extraction to address the urgent need of a reliable hazard assessment of food for low income countries including toxicity testing.

WE002
AMINOGLYCOSIDES ANTIBIOTICS RESIDUES ANALYSIS IN BOVINE MILK AND BOVINE, SWINE AND POULTRY MUSCLE BY LC-MS/MS AND LC-QTOF-MS: A SIMPLE AND FAST NON SPE METHOD
j. bazzan arsand; L. Jank, Federal University of Rio Grande do Sul / Chemistry; M.T. Martins, Ministry of Agriculture; R. Hoff, Ministry of Agriculture / RPM; F. Barreto, Ministry of Agriculture; C. Sirtori, Federal University of Rio Grande do Sul / Chemistry; T. Pizzolato, Federal University of Rio Grande do Sul / Department of Analytical Chemistry; S. Diaz-Cruz, IDAEA-CSIC / Environmental Chemistry; D. Molins Delgado, IDAEA-CSIC; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry
The presence of several different substances in animal products has been a major public concern. The use of antibiotics drugs as veterinary medicines might lead to the development of bacterial resistance, which might undermine the efficacy of these drugs in human use. The Brazilian government implemented a control plan that assesses the residues of veterinary medicines in animal products. The aminoglycosides are antibiotics that have been extensively employed in animal husbandry for the treatment of bacterial infections, but also as growth promotion. The European Union has issued strict maximum residue levels (MRLs) for aminoglycosides in several animal origin products. An analytical method has been developed for determination of ten aminoglycosides (spectinomycin, tobramycin, gentamicin, kanamycin, hygromycin, apramycin, streptomycin, dihydrostreptomycin, amikacin and neomycin) in bovine milk and bovine, swine and poultry muscle. A simple, fast, cheap and ecofriendly extraction method with non SPE steps was developed using trichloroacetic acid and clean up with low temperature precipitation and C18 bulk. A 2^4 factorial design with center point was performed to assess changes in the steps of the extraction process and the best condition was adopted. The LC–MS/MS and LC-qTOF-MS methods were validated according to the European Union Commission Directive 2002/657/EC. Good performance characteristics were obtained for recovery, precision, calibration curve, specificity, decision limits (CCα) and detection capabilities (CCβ) in all matrices tested. The data detection limit (LOD) and limits of quantification (LOQ) was established from MRL ranging from 5 to 100 ng g^{-1} for LOD and 12.5 to 250 ng g^{-1} to LOQ. Good linearity (r^2) above 0.99, considering three different days, for all aminoglycosides was achieved in concentrations ranging from 0.0 to 2.0 x MRL, noting that all curves have been made into their own matrices in order to minimize the effects matrix which are intrinsic to the cases studied in this work. Recoveries ranged from 36 to 98% and the coefficient of variation from 0.9 to 20.2%. The CCβ values obtained in qualitative method were between 25 and 250 ng g^{-1}, considered satisfactory for the analytes in those matrices. The proposed method proved to be simple, easy, and adequate for high-throughput analysis of a large number of samples per day at low cost.

WE003
Levels of pharmaceuticals and endocrine disruptors in commercially available seafood before and after cooking
D.A. Muñoz, Catalan Institute for Water Research ICRA / Water Quality; S. Rodriguez-Mozaz, Institute for Water Research (ICRA) / Water Quality; A. Serra, ICRA Catalan Institute for Water Research / Water Quality; N. Caceres, Catalan Institute for Water Research ICRA / Water Quality; J. Williamson, Colorado School of Mines / Chemistry and Geochemistry; I. Sioen, K. Verbeke, University of Ghent; A. Maulvault, IPMA, I.P. / Division of Aquaculture and Seafood Upgrading; A. Tediosi, AEIFORIA; M. Fernandez-Tejedor, Institute of Agriculture and Food Research and Technology; S. Cunha, University of Porto; K. Granby, DTU Technical University of Denmark; J. Robbens, Institute for Agriculture and Fisheries Research; M. Kotterman, IMARES / Fish; A.M. Marques, Portuguese Institute for the Sea and Atmosphere / Division of Aqiaculture and Upgrading; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry
Research has shown that eating fish and selfish regularly is beneficial to our bodies in many ways. However, it can also be a source of harmful environmental contaminants with potential to impact negatively on human health. The presence of "contaminants of emerging concern" like pharmaceuticals and endocrine disrupting compounds in seafood for human consumption needs to be monitored. Besides, to study the effect of cooking and processing on contaminants levels in seafood becomes a relevant issue since it has been observed that an increase in the concentration may occur. Therefore, the main objectives of this study were to detect the possible presence of pharmaceuticals and endocrine disruptors in seafood, to investigate the effect of cooking on contaminants levels, and to establish whether the measured concentrations were below the maximum levels set by the European Union. Besides, a risk assessment was performed in order to evaluate the human health impact of the contaminants present in seafood. An European sampling survey of seafood collected in different European regions have been carried out.Several commercial seafood species including seabream, mackerel, tuna, salmon and mussels have been sampled on different seasons (autumn and spring time) and geographic locations (Spain, Italy, Portugal, Denmark, Norway, Netherlands and France). Based on previous results a list of priority PhACs and EDCs was targeted. The presence of compounds such as diclofenac, diazepam, sotalol, carbamazepine, citalopram, venlafaxine, azithromycin and sulfamethoxazole, TBEP, bisphenol A, and triclosan was researched. In the majority of the samples analysed PhACs compounds were nor detected or below method quantification limits. In few ocassions positive

identification of some pharmaceuticals was done reaching up to 11.7 ng/g dry weight of sulfamethoxazole in mussels from Netherlands. Regarding EDCs methylparaben, triclosan, and bisphenol A were frequently detected in seafood. Besides, an increase in these contaminants levels was observed after cooking by steaming. The highest level measured correponded to bisphenol A in canned tuna reaching up to 69.1 ng/g dw. Due to their presence and levels in seafood methylparaben, triclosan, and bisphenol A were selected for performing risk assessment, and for researching whether intake of these contaminants through seafood consumption involves a risk for human health. This piece of research is currently ongoing and results will be presented at the meeting.

WE004

Heavy metals in freeze dried milk from Brazil

D.A. Rocha, A.D. Netto, Universidade Federal Fluminense / Quimica; J. Torres, Radioisotopoes Laboratory / Environmental Biophysics

The production of milk in Brazil is one of the most important rural activity involving and more than 30 billion of liters being produced each year. Essential food for different but important population groups like children and the elderly, milk is an invaluable source of important micronutrients like zinc, copper and iron. However mineral supplementation or even corrosion in metallic equipment may also represent a source of non-essential and toxic elements, like mercury, cadmium and lead that may sometimes be a route of contaminants to human beings. Since soil particle ingestion is frequently observed during cattle grazing, our objective with this study is to determine if the levels of this elements in freeze dried milk can reveal a route for the transference of the selected metals to man. Around two grams of freeze dried milk where analyzed in triplicates after calcinations (450 ºC) and acid digestion in hot-plates. All measurements were performed at the Radioisotopes Laboratory of the Biophysics Institute of the Federal University of Rio de Janeiro. In spite some cases of contamination by Fe in some imported brands of milk in powder; the recurrent problem in Brazil is milk adulteration by addition of caustic soda and formaldehyde in the production of UHT milk. As expected, there is a higher contribution of Zn in the overall results, indicating once more that milk is an important source of this micro-element. Although most farms are equipped with stainless steel devices for refrigeration and storage, the use of less noble steel more fond of corrosion can be considered a source of toxic metal contamination, especially Ni and Cr. As for Pb, this metal may be present in anticorrosive paint. In the present study, with only few exceptions for Cr and Pb, the determined values were not higher than the provided maximum allowance for the agricultural Brazilian legislation. In the absence of new voltametric and anodic stripping methods for direct measurements of the metallic contents of milk, the so called *old fashion* methods are still a choice and can help in the characterization of the inorganic contamination of dairy products. More research is needed to clarify the relation on proper maintenance of metal equipments, soil contamination and milk quality in order to acquire better standard production parameters for milk source qualification, in the view of an organic farmer green product verification/certification.

WE005

UV filters maternal transfer through breastfeeding

D. Molins Delgado, IDAEA-CSIC; M. Olmos, IDAEA-CSIC / Environmental Chemistry; G. Valeta, Banc de Sang i Teixits; S. Diaz-Cruz, IDAEA-CSIC / Environmental Chemistry; D. Barcelo, IIQAB-CSIC / Dept Environmental Chemistry

Organic UV filters are the preferred protection against adverse effects of UV radiation in all kind of cosmetics, as well as in common materials and industrial products. This fact leads to a continued human exposure. Many studies show the tendency of UV-F to bioaccumulate in living organisms due to their lipophilicity and stability versus biotic degradation [1]. The extended use and the ubiquity of these compounds in the environment make necessary studies on the bioaccumulation in human tissues and elimination from the body of these compounds through biological fluids. Breast milk is a biological fluid that has a fundamental role in new born nutrition and has direct impact on growth, neurodevelopment and health [2]. Breast milk is a compositionally variable fluid that is known to change during the lactation period, and it is highly influenced by maternal dietary intake and life style. In this framework, the aim of this study was to assess the potential maternal transfer of UV filters to newborn through breastfeeding. BP3, BP1, 4HB, 4DHB, OD-PABA, OC, EHMC, Et-PABA , BZT, TBHPBT, UV320, UV329, 4MBC and MeBZT were the UV filters investigated. Breast milk samples, provided by mothers from Barcelona were first extracted by USE and after internal standard addition, analysed by Turbulent Flow-Chromatography-HPLC-MS/MS. Results indicated that 7 out of the 14 UV filters investigated were detected in the 79 milk samples analysed. 28 samples were positive in at least one compound. BP3 was the most frequently detected compound (68%) and the one observed at the highest concentration, 1599.8 ng/g milk. Two human metabolites of BP3, 4HB and 4DHB, were also identified in the samples. Finally, we concluded that breast milk samples contained a number of UV filters, mostly BP3 and two of its human metabolites, which suggest that not only UV filters are accumulated but also the more polar metabolites formed. During breastfeeding mother “eliminates” its own contamination but transfer it to the neonate. References [1] Kim JW, Ramaswamy BR, Chang KH, Isobe T, Tanabe S. 2011. J Chromatogr A 1218: 3511-3520. Polybrominated Diphenyl Ethers and Polychlorinated Biphenyls in Breast Milk from Serbia First-Time Mothers

J. Milic, Institute of Chemistry, Technology & Metallurgy / Centre of Chemistry; N. Lugonja, T. Šolević Knudsen, Institute of Chemistry, Technology & Metallurgy, University of Belgrade / Centre of Chemistry; V. Marinkovic, University Childrens Hospital, Belgrade / Neonatology Department; T. Nakano, Research Center for Environmental Preservation, Osaka University; T. Hirai, Otsuka Pharmaceutical Co / Otsuka Life Science Initiative; K. Kakimoto, Osaka Prefectural Institute of Public Health; M.M. Vrvić, Faculty of Chemistry, University of Belgrade / Faculty of Chemistry

Polybrominated diphenyl ethers (PBDEs) and polychlorinated biphenyls (PCBs) are two highly lipophilic classes of persistent organic pollutants (POPs) able to resist degradation and with the ability to bioaccumulate through the food chain. The international community has responded to the threat from POPs by negotiating a global treaty, the Stockholm Convention on POPs, with the objective of protecting human health and the environment from POPs. Human milk may provide a significant source of exposure to POPs in early life, and data on levels of POPs in breast milk from different regions of the world have been generated in many publications. However, a little is known about levels of POPs chemicals in milk of Serbian mothers, especially concerning PBDEs. Objective of study was to investigate contamination of PBDEs and PCBs in breast milk from Serbia. A total of 11 breast milk samples from the first time mothers were collected in Department of Neonatology in Belgrade, Serbia from November 2014 to April 2015. Total lipids from breast milk samples were extracted by Soxlet method (ISO 8262-1) and subsequently the PCB and PBDE congeners were analyzed by HRGC/HRMS. Average concentration of PBDEs in samples was 753,8 pg/g fat, with highest share of BDE #47 more than 40%. Average concentration of PCBs in samples was 79,8 ng/g fat, with highest share of PCB #153 more than 14%. The PBDE (#17, #28, #47, #99, #100, #153 and #154) and PCB (#28, #52, #77, #81, #101, #105, #114, #118, #123, #126, #138, #152, #156, #157, #167, #168, #180, #189) contamination in breast milk as well as congener profiles was comparable to those in other neighbour countries in region. These results represent first published data of PBDE contamination of human milk in Serbia. Considering human milk’s nutritional and immunologic effects, society must take steps to decrease human exposure to these chemicals by restrictions in their usage, while continue encouraging women to practice breastfeeding.

WE007

Using RISK21 matrix to assess the potential human health risk of DDT exposure from flower tea

Y. Lin, P. Lin, S. You, W. Chou, Z. Weng, National Health Research Institutes / National Institute of Environmental Health Sciences

The Health and Environmental Science Institutes-coordinated RISK21 is an integrated evaluation strategy which provides a straightforward, efficient, systematic, and transparent way for health risk assessment. RISK21 takes advantage of existing information to graphically represent the comparison of exposure and toxicity data on a highly visual matrix, termed RISK21 matrix. Recently, the long-banned pesticide DDT (dichlorodiphenyltrichloroethane) and its metabolites were found in the rose leaves as the flower tea drinks sold at Taiwan's popular tea chain store. The purpose of this study was to adopt RISK21 approach to assess the degree of health risk of DDT exposure from drinking flower tea or directly consuming rose leaves. Based on the foundation of risk assessment, we integrated the estimates of age-specific total daily intakes (TDI) of DDT with toxicity data on liver lesions and developmental toxicity to assess the level of health concern by RISK21 matrix. The TDIs through direct intake of flowers for various age groups were estimated based on the concentrations of DDT, DDD (dichlorodiphenyldichloroethane), and DDE (dichlorodiphenyldichloroethylene) in rose leaves as well as age-specific intake rate of flower tea, whereas additional factors of compound-specific water solubility and dilution factor on the flower tea were taken into account to calculate the TDIs from flower tea drinks. By considering the uncertainties of TDI estimates and toxicity estimates, Risk21 matrix shows that drinking DDT-contaminated flower tea seems unlikely to constitute a public health and safety concern for all age groups due to the extremely low exposure level. However, the human health risks of DDT exposure are alarming from a conservative point of view in regards to direct intake of flowers. RISK21 matrix is an easy-to-use tool that not only promotes the understanding of risk assessment but also fosters the risk communication.

Interactions between traditional, novel and green carbonaceous materials and contaminants (P)

WE008
Removal of 2,4-dinitrotoluene and 2,4-dichlorophenol with zero-valent iron-embedded biochar
S. Oh, University of Ulsan / Department of Civil and Environmental Engineering; Y. Seo, University of Ulsan / Civil and Environmental Engineering
Removal of 2,4-dinitrotoluene (DNT) and 2,4-dichlorophenol (DCP) with zero-valent iron [Fe(0)]-embedded biochar was investigated as a possible in-situ remediation process. Fe(0)-embedded biochar was synthesized using rice straw via slow pyrolysis and its properties were characterized. DNT and DCP were chosen as model contaminants and their kinetics and mechanisms were examined through a series of batch experiments. Compared to reduction control by Fe(0) and sorption control by biochar, the removal by Fe(0)-embedded biochar was significantly enhanced, indicating that biochar plays a role of sorbent as well as electron-transfer mediator. Increasing pyrolysis temperature resulted in promoting the removal rate of the contaminants, suggesting that rather than surface functional groups, aromaticity of biochar may account for the catalytic role. According to yields of reduction products, the presence of biochar showed difference reduction pathways. Applicability of Fe(0)-embedded biochar in natural and engineered systems was also discussed.

WE009
Supporting of PAHs bioavailability and ecotoxicity reduction by nano zerovalent iron (nZVI) and biochar in industrially contaminated soils
M. Kołtowski, P. Oleszczuk, Maria Curie Skłodowska University / Department of Environmental Chemistry
Polycyclic aromatic hydrocarbons (PAHs) are organic contaminants which are harmful for humans and other organinsms. One of the source of this contaminants is industry e.g. coal and bitumen production. The emitted PAHs can migrate into soil where they can accumulate in biota and negatively affect organisms. Due to this fact, there is a need of providing efficient tool for remediation of industrially contaminated soils by PAHs. One of the current remediation strategy of contaminated sites by PAHs is using a biochar as a sorbent for PAHs immobilization. To enhance the biochar PAHs reduction in contaminated soils, we supported soil remediation by nano zerovalent iron (nZVI), known from its effectiveness in the organic contaminants degradation. Therefore, two types of soils were investigated in this study: 1) KOK soil - sampled from the area of coking plant (Dabrowa Górnicza, Poland), and 2) POPI soil – sampled from the area of bitumen processing plant (Wólka Lancuchowska, Poland). Moreover, biochar produced from the wheat straw (BCS) and nano zerovalent iron, were used. Each soil were amended by BCS or/and nZVI in few variants: 1) by nZVI with a dose of 2 and 10 g_{nZVI}/kg_{soil} as a water suspension, 2) by biochar BCS with a dose of 5% w/w and equal amount of water needed for preparation of nZVI suspension, and 3) by nZVI with a dose of 2 and 10 g_{nZVI}/kg_{soil} as a water suspension together with biochar at a dose of 5% w/w. Pure soils samples amended with water as in 2) were taken as a control. Prepared samples were rolled end over end at 10 rpm for 7 or 30 days in dark and at room temperature. After 7 and 30 days, chemical and ecotoxicological analysis were carried out. Freely dissolved concentration of PAHs (C_{free}) was assessed by polyoxymethylene (POM) and ecotoxicity was determined using *Vibrio fisheri* bacteria (Microtox). Application of pure biochar and biochar together with nZVI to contaminated soils decreased a PAHs C_{free} and its potential environmental risk to the organisms. We also observed negative effect of decreasing bacteria bioluminescence after pure nZVI amendment to soils (especially in case of KOK soil). Nevertheless, combined addition of biochar and nZVI resulted in elimination of toxic effects of nZVI. Moreover, this variant in most cases showed the highest reduction of ecotoxicity and also provoked stimulation effects of bioluminescence in both soils.

WE010
Sorption of aromatic hydrocarbons to biochars
M. Kah, H. Sun, T. Hüffer, T. Hofmann, University of Vienna / Department of Environmental Geosciences
Many studies have demonstrated the strong sorption potential of biochars towards organic contaminants. Our ability to predict the extent of sorption for a given situation is however very limited, mainly because the effects that sorbate and sorbent properties have on sorption remain poorly understood. With the aim to support the development of predictive approaches, we systematically compared the sorption behavior of a series of biochars produced from different feedstock and at different pyrolysis temperature. All sorbents were extensively characterized and cover a wide range of properties that were previously identified as possible drivers for sorption (e.g., elemental composition, surface area, micro and mesoporosity). A series of aromatic hydrocarbons covering a range of molecular sizes were selected as sorbates (i.e., from benzene to pyrene). The sorption behavior of aromatic hydrocarbons is relatively well understood and allows investigating how the surface and porosity characteristics of the biochars affect sorption behavior. Sorption isotherms were measured across a concentration range covering several orders of magnitude. The Freundlich model fitted all isotherms very well, and non-linearity significantly increased with the pyrolysis temperature. The dual-mode model also proved useful to fit sorption isotherms and compare the contributions of solvent-driven and sorbent-driven processes (described by linear and Langmuir model, respectively). Multivariate analyses were also applied to identify the factors driving the great differences in sorption observed. Overall, the results provide a better understanding of the effects that biochar properties have on sorption behavior and thus possibly identify groups of biochars, whose sorption behavior could be described using common approaches.

WE011
Adsorption of Polychlorinated biphenyls to activated carbons with different surface and textural properties
O.R. Idialu, C. Davidson, University of Strathclyde / pure and applied chemistry; A. Fletcher, University of Strathclyde / chemical and process engineering; L. Gibson, University of Strathclyde / pure and applied chemistry
Activated carbon is a commonly used sorbent for the removal of organic pollutants from waters and industrial effluent streams. Although several studies have been conducted on the removal of persistent organic pollutants (POPs) from aqueous solutions using activated carbon, very little attention has been given to polychlorinated biphenyls (PCBs). In addition, the sorption efficiencies of PCB congeners on activated carbon with different surfaces and/or textural properties have not been fully explored. In this study, the sorption of PCB congeners from aqueous solutions to powdered activated carbon (PAC) or granular activated carbon (GAC) was studied experimentally using batch adsorption. The five target PCBs under investigation were PCB -1, 3, 7, 14 and 12. The efficiency of solid phase extraction (SPE) for pre-concentration was assessed using C18 (EC) or florisil SPE cartridges. Results obtained showed that C18 (EC) SPE cartridges provided higher extraction efficiencies (38 - 46 %) for the target PCBs compared to florisil SPE cartridges (9 -16 %). Investigation of the removal efficiency of PAC and GAC for PCB congeners was studied using a fixed mass of sorbent and varying initial PCB concentrations. GAC was found to have higher removal efficiency (33 – 63 %) for the target PCB congeners compared to PAC (50 – 96 %). Langmuir and Freundlich adsorption isotherms were applied for the analysis of equilibrium data. The correlation coefficients (r^2) obtained showed that the Langmuir model, in the linear form, adequately fitted experimental data for both PAC and GAC. The total PCB adsorption capacities of PAC and GAC obtained using predicted q_m values from the Langmuir model were 26.93 and 26.2 mg/g respectively.

WE012
Effects of Carica papaya seeds biochar and its Goethite modified amendments on Lead mobility in soil
B.I. Olu-Owolabi, B. Agbaogun, O.A. Oluyinka, University of Ibadan / Department of Chemistry
Presence of heavy metals (HM)-most especially Pb, in the environment has been worrisome because of its health implications on man and other biota. The labile fraction of HM in contaminated soils is however the most important. It is the portion that is readily available for plant uptake, thus accumulates in plants and eventually gets to humans who consume the plants. Therefore, any efforts that could lead to immobilization of HM in contaminated soils should be of uttermost scientific interest. This study reports the effects of Carica papaya seeds biochar (CB) and Goethite modified Carica papaya seeds biochar (GCB) on the mobility of Pb in a contaminated soil from the abandoned dump site of the defunct Exide-battery Manufacturing Company at Lalupon, Southwestern Nigeria. Ten treatments pots (in duplicates) were set up with the soil sample. First pot contained the sample at 0% amendment, and this served as the control. The second, third and fourth pots were amended with CB at 2%, 5% and 10% levels respectively; the fifth, sixth and seventh pots were amended with 5% Goethite modified CB (5%GCB) at 2%, 5% and 10% levels respectively, while the eighth, ninth and tenth pots were amended with 10% Goethite modified CB (10%GCB) also at 2%, 5% and 10% levels respectively. All treatments were brought to the field capacity with deionized water, and then incubated at room temperature for 30 days. The field capacity moisture was maintained throughout this period. At the end of the incubation period, 1g of the sample was extracted with 1M $MgCl_2$ solution, and the Pb content was measured with AAS. The $MgCl_2$-extractable Pb content of the control was found to be 1680mg/Kg. This was reduced by 80-89% by CB, 90-98% by 5%GCB, and 70-90% by 10%GCB. In conclusion, all the additives significantly reduced the bioavailable Pb in the soil, with the 5%GCB being the best, followed by CB. This has opened further opportunities for similar researches with other agricultural biomass. Keywords: Heavy metals, Carica papaya, Biochar, Goethite

WE013
Sorption of substituted aromatic hydrocarbons by fullerenes - Influence of functionalization on molecular interactions
T. Hüffer, H. Sun, M. Kah, T. Hofmann, University of Vienna / Department of Environmental Geosciences
The interpretation and prediction of molecular interactions between organic compounds and carbon-based nanomaterials is of major importance to understand phase transfer processes in environmental matrices and to assess the potential application of these materials as special sorbent materials. While there is a lot of sorption data available for carbon nanotubes, little information is available on the

sorption behavior of C60 fullerenes. In a previous study we have investigated the effect of UV-induced surface oxidation on sorption behavior of C60 [1]. Changes in surface chemistry led to significant alteration in both sorption capacity and affinity. The results indicated that in addition to non-specific van-der Waals and electron donor-interactions, the presence of −OH and −COOH groups on C60 surface potentially allowed for the contribution of hydrogen-bonds. However, sorption data for a much broader set of probe compounds, covering various chemical classes, are necessary to further investigate the contribution of individual interactions to overall sorption. To systematically study this process, the combined effects of -OH/NH_2 functional groups of aromatic organic compounds and surface O-containing groups on C60 on the interactions were evaluated. We combined two multi-phase sorption batch experiment approaches using a passive sampling technique applying polyoxymethylene and a headspace in-tube microextraction. This allows for an systematic comparison of the interactions between C60 and organic compounds with significantly different physico-chemical properties (e.g., aromaticity, functional groups, etc.). [1] Hüffer T., Kah M., Hofmann T., Schmidt T.C. 2013. Environ Sci Technol 47: 6935-6942.

WE014

Immobilization of organic contaminants and heavy metals by carbonized sorbents - mechanisms and prediction

G. Sigmund, H. Sun, T. Hüffer, M. Kah, T. Hofmann, University of Vienna / Department of Environmental Geosciences

Carbonized sorbents typically comprise only a small proportion of the soil or sediment matrix. However, they do significantly enhance sorption affinity and capacity of contaminants. Hence, carbonized sorbents are commonly used for the immobilization of both organic contaminants and heavy metals. Depending on the contaminant group, different interactions drive sorption, and different parameters may be used to predict the sorption potential of a given carbonized sorbent for a given contaminant. Therefore, the aim of this study was to identify (i) interactions that drive sorption and (ii) key parameters for the prediction of sorption for neutral organic contaminants, organic acids and heavy metals. Hence, we combined comprehensive characterization of selected carbonized sorbents with data from sorption batch experiments for selected polycyclic aromatic hydrocarbons, organic acids and heavy metals. Generally, sorption strength (K_D, kg/L) followed: polycyclic aromatic hydrocarbons > heavy metals ≥ organic acids. We found that the immobilization of neutral organic contaminants can occur via hydrophobicity driven interactions and specific interactions (i.e. π-π electron interactions and H-bonds), and depends on various factors including the grade of carbonization and availability of sorption sites. The immobilization of organic acids can additionally occur via electrostatic interactions and cation bridging and depends on factors including ionic strength and solution pH. The immobilization of heavy metals can occur via specific and non-specific electrostatic interactions, exchange, and precipitation, and depends on factors including ionic strength, pH and redox-conditions. The sorption of neutral and acidic organic contaminants can be well predicted by combining parameters commonly used to describe sorbent and sorbate properties, i.e. specific surface area, and octanol-water partitioning behavior (K_{OW} and D_{OW} for neutral and acidic compounds, respectively). For the prediction of heavy metal sorption, a case by case evaluation is needed, due to the complexity of factors influencing speciation and precipitation processes. Our findings help better predict the sorption potential of carbonized sorbents to a large range of contaminant groups. For neutral and acidic organic contaminants we present a simple assessment tool for the potential use of carbonized sorbents in environmental applications.

Vicia-micronucleus test as a newly standardized tool to assess soil genotoxicity: Application to the evaluation of the effects of biochar in contaminated soils

S. COTELLE, LIEC - Université de Lorraine - CNRS; F. REES, LSE - INRA - Université de Lorraine; A. DHYEVRE, LIEC / Laboratoire Interdisciplinaire des Environnements Continentaux; J. MOREL, LSE - INRA - Université de Lorraine; S. MULLER, LIEC   Université de Lorraine   CNRS

The risk assessment of industrial contaminated soils is an important challenge in remediation process. Information on bioavailability of pollutants requires the development of biological tests, especially with plants. Ma (1999) described higher plants as the most sensitive organisms for the detection of mutagens and genotoxic effects of environmental pollutants. Although ecologically relevant for soil toxicity assessment, plants are surprisingly not the most commonly used organisms for genotoxicity tests (White and Claxton, 2004). This is the reason why genotoxicity tests with higher plants have been promoted (IPCS – United Nations Environment Programme, 1999). Genotoxicity - simply defined as the toxicity on the genome - is an indicator of dysfunctions appearing at sub-lethal concentrations. An easy endpoint to observe is the formation of micronuclei, that are small nuclei appearing whenever a chromosome fragment or a complete chromosome is not incorporated into the nuclei during mitosis. This endpoint is very important to include in a battery of ecotoxicity tests for a better risk assessment of contaminated soils and of the impact of remediation techniques applied to them. Among techniques of *in situ* remediation, soil amendments with biochar, *i.e.* the solid product from biomass pyrolysis, have recently been investigated for decreasing the bioavailability of metals in industrial soils. Biochar has been shown to immobilize metals both by direct sorption at its surface and by an indirect effect through an increase of soil pH (Rees et al., 2014). The effect of biochar on the actual genotoxicity potential of metal-contaminated soils is however unknown. The aim of this study was to assess the genotoxic potential of a range of soils contaminated by heavy metals (Zn, Pb, Cd) and amended by a wood-derived biochar to create a gradient of metal availability. We recently obtained international standardization of the *Vicia*-micronucleus test (ISO 29200) in 2013 and we performed it in this study by direct exposure of root tips to soils. The analysis of root morphology and root metal content completed the experiment. Results showed that these industrial soils induced genotoxicity, revealed by an increase of micronuclei frequency. Their genotoxic potential strongly decreased with the addition of biochar. Relationships between genotoxicity, soil metal extractability and root metal content will be discussed.

WE016

Modulation of metal bioavailability for two earthworm species by the use of biochar

L. Marchand, INRA Institut National de la Recherche Agronomique / UMR BIOGECO; S. Brunel-Muguet, UNICAEN / UMR Ecophysiologie Végétale Agronomie et nutritions; C. Mougin, INRA (Institut National de la Recherche Agronomiqu / UMR ECOSYS; I. Lamy, INRA Institut National de la Recherche Agronomique / UMR ECOSYS; Q. Zhang, Chinese Academy of Agricultural Sciences / Key Laboratory of Agricultural Environment; M. Mench, INRA Institut National de la Recherche Agronomique / UMR BIOGECO; C. Pelosi, INRA Institut National de la Recherche Agronomique / UMR ECOSYS

Anthropic activities may lead to depletion in soil organic matter contents and to soil contamination, particularly by trace elements. Biochars i.e. stable carbon-rich by-products synthesized through pyrolysis/carbonization of plant- and animal-based biomass, are used as soil amendments to improve carbon sequestration and crop yields while valorizing crop residues and stabilizing soil contaminants. The aim of this study was to assess the effect of a poultry manure-derived biochar on the bioavailability of cadmium (Cd), copper (Cu), lead (Pb) and zinc (Zn) for two earthworm species i.e. *Aporrectodea icterica* and *Aporrectodea longa* exposed in microcosms to an *in situ* contaminated soil during 28 days. For that purpose, we assessed (i) the environmental availability by measuring total concentrations and concentrations in pore water, (ii) the environmental bioavailability by measuring concentrations of trace elements in earthworms, and (iii) the toxicological bioavailability by measuring survival, weight gain, energy reserves (protein, lipid and glycogen contents) and the GST (glutathione-S-transferase) enzymatic activity of earthworms, as an indicator of detoxification processes. Contrary to what we expected, the presence of the studied poultry manure-derived biochar did not greatly influence the bioavailability of trace elements for earthworms under our conditions. We discussed assumptions to explain these results.

WE017

Modulation of trace element bioavailability, yield and seed quality of rapeseed (Brassica napus L.) by biochar addition to a contaminated technosoil

L. Marchand, INRA Institut National de la Recherche Agronomique / UMR BIOGECO; C. Pelosi, INRA Institut National de la Recherche Agronomique / UMR ECOSYS; C. Mougin, INRA (Institut National de la Recherche Agronomiqu / UMR ECOSYS; M. Gonzalez Centeno, Université de Bordeaux / Unité de recherche Oenologie; A. Maillard, A. Brunel-Muguet, UNICAEN / UMR Ecophysiologie Végétale Agronomie et nutritions

Rapeseed (*Brassica napus* L.) is a Cd/Zn-accumulator whereas soil conditioners such as biochars may immobilize trace elements. These potentially complementary soil remediation options were trialed, singly and in combination, in a pot experiment with a metal(loid)-contaminated technosol developed on dredged sediments. The efficiency of these remediation options were assessed using both phenotypic and physiological plant responses. A trace element (Cd, Cu, Pb, Zn) contaminated technosol was either amended (2% w/w) or not with a poultry manure-derived biochar. Rapeseed was cultivated under both soil treatments during 24 weeks up to harvest in greenhouse. Based on the soil pore water, biochar incorporation into the technosol promoted the As, Cd, Cu, Mo, Ni, Pb and Zn solubility. It decreased foliar B, Cu and Mo concentrations, and Mo concentration in stems, pericarps and seeds. Conversely, it did not impact neither the biomass of aerial rapeseed parts (except a decrease for seeds), nor their C content (except a decrease for stems), seed fatty acid content, seed sugar content

and antioxidant capacity in both leaves and seeds. Biochar amendment increased the phytoextraction by aerial plant parts for K, P, and S, reduced it for N, Ca, B, Mo, Ni and Se, whereas it remained steady for Mg, Zn, Fe, Mn, Cu, Cd and Co. Zinc and Cd concentrations in the soil pore water were decreased 3 times by rapeseed in the unamended technosol showing the feasibility to strip available soil Zn and Cd in combination with seed production.

WE018

Rearing kids on chlordecone contaminated soils: Activated carbon, a promising media to limit the transfer from soil to animal tissues

S. Yehya, Universite de Lorraine / Unité de Recherche Animal et Fonctionnalités des Produits Animaux URAFPA; M. DELANNOY, URAFPA-INRA / Unité de Recherche Animal et Fonctionnalités des Produits Animaux URAFPA; A. Fournier, G. Rychen, Universite de Lorraine / Unité de Recherche Animal et Fonctionnalités des Produits Animaux URAFPA; C. Feidt, Université de Lorraine - UL / Unité de Recherche Animal et Fonctionnalités des Produits Animaux URAFPA

Chlordecone (Kepone) (CLD) is a highly persistent pesticide in soil which was intensively used in French West Indies to fight the banana black weevil. Because of its toxicity and considerable levels in soil, it became a major threat for human health to address . Soil or sediments are considered as reservoir for this contaminant and soil ingestion is the main exposure route for free range animals. In order to ensure the production of safe animal foodstuffs, it is necessary to reduce the transfer from soil to animal tissues. The present study intends to test whether two different activated carbons (ACs) could limit the CLD transfer from soil to animal. Three artificial soils (ASs) were prepared according to OECD guideline 207. One standard soil (SS), devoid of organic matter (OM), and two amended versions of this SS with coconut-based activated carbon (AC_1) or lignite-based one (AC_2) were prepared to obtain a 2% organic carbon content (dry matter basis). This study involved 15 kids as a typical on-farm consumption animal. Animals were randomly distributed into 3 groups (n=5 replicates). During 21 days, the kids were fed AS spiked with 10 μg of CLD per g of dry matter to achieve an exposure dose of 10 μg CLD per kg of body weight per day. After 21 days of oral exposure, CLD in peri-renal adipose tissue and liver were analysed by GC–MS, after extraction and purification. Concentrations in tissues were significantly affected by the treatment (p< 0.01). In liver, CLD concentration was 2110, 450 and 24 ng.g-1 DM for SS, AC_1 and AC_2 respectively. This decrease corresponds to a relative bioavailability of 21 and 1.2% for AC_1 and AC_2 respectively. In adipose tissue, a similar decrease has been observed. This study leads to conclude that 1/ AC could dramatically reduce the bioavailability of CLD 2/ extent of this limitation depends of the nature of AC. This result obtained with artificial soils is considered as a first major step prior to on-field experiments.

WE019

PAHs in biochars are largely desorption resistant

I. Hilber, Agroscope ART

When biochar is applied in agricultural practice polycyclic aromatic hydrocarbons (PAHs) that are coproduced during the feedstock pyrolysis might be released into the environment. It is therefore important to assess the exposure of the native PAHs in this carbonaceous material for humans and the living environment. We report on the PAH exposure of almost 50 different samples including biochars from different feedstocks, pyrolysed under increased oxygen content and mixtures of biochar and organic material. The total concentration ($C_{total} = C_S$) in the samples ranged from 0.4 to almost 2000 mg/kg$_{dry\ weight\ (dw)}$ and the freely dissolved concentration ($C_{free} = C_W$) from 4 to 81 ng/L for the sum (?)16 PAHs. High partition coefficients of the single PAH compounds ($K_D = C_S/C_W$ ranged from 10^4 to 10^9) lead to C_{free} of the pure biochar samples below ambient levels. These high K_Ds make a direct determination of the bioaccessibility (the concentration of the pollutant accessible for organisms over a relevant time span) difficult if not impossible, whereas desorption-resistant PAH concentrations can be determined. Therefore, a set of samples was exposed to contaminant traps in which cyclodextrin served as diffusive carrier and a composit of activated carbon and silicone as infinite sink.[1] These biochar samples were then recovered and the remaining PAHs extracted. Bioaccessibility was then calculated as concentration difference between biochars with and without exposure to the traps. Bioaccessibility of PAHs could be measured in 21% of the samples (the others showed 100% desorption resistant PAHs). The bioaccessible concentration of for instance BaP, the most carcinogenic PAH, was up to 2.8 mg/kg in a pure biochar that contained a C_{total} of 281 mg/kg$_{dw}$?16 PAHs. Nonetheless, the majority of the samples showed bioaccessible concentrations of BaP < 0.1 mg/kg. Although bioaccessibility was low in terms of numbers of observation, it was in some cases significant in terms of absolute concentrations. Biochar manufacturers are therefore encouraged to follow guidelines to minimize PAH formation during production. (1) Mayer, P.; Olsen, J. L.; Gouliarmou, V.; Hasinger, M.; Kendler, R.; Loibner, A. P. In order to meet the proposed quality criteria and European soil and water protection targets, biochar characterization requires an integrative framework that includes analytical and effect-based approaches. Three contrasting biochars produced from mixed wood sieving (BW), paper sludge and wheat husks (BPS) and sewage sludge (BSS) according to current quality guidelines, were characterized for physical, chemical and ecotoxicological properties, in an interdisciplinary initiative of the biochar COST Action TD1107. It aimed at assessing their impact on the soil habitat function, when applied to natural (peat, Lufa 2.2) or standard (OECD soil) substrates at application rates relevant to agricultural and/or environmental management (0, 10, 50, 100, 200 t/ha). Avoidance behaviour, survival and reproduction bioassays were performed, with soil invertebrates *Eisenia andrei* (Oligochaeta) and *Folsomia candida* (Collembola), which are representative of different ecological functions. Seed germination and growth of model crop species with socio-economic relevance (*Hordeum vulgare*, *Lactuca sativa*) were also evaluated based on test procedures adapted for biochar phytotoxicity assessment. Avoidance behaviour tests showed preference by earthworms and collembolans for BW and BPS at 10 and 50 t/ha, with no preference or avoidance behaviour for BSS. There were also no significant effects on collembolan survival and reproduction (nº of produced juveniles). Plant bioassays showed that BW and BPS addition (at ca. 330 t/ha mixed to 30 cm depth) increased fresh biomass, indicating that negative effects were absent even at unusually high biochar addition rates for agricultural applications. Overall, the absence of lethal and sub-lethal detrimental effects on the test invertebrates and plants suggests a low risk to soil biota and the soil habitat function, upon amendment with the selected biochars. This result is consistent with extensive biochar analytical characterization data, as determined by state-of-the-art methodologies. We hereby demonstrated the suitability of a battery of soil ecotoxicological assays, as a complement to biochar characterization and a tool to prevent/manage possible risks to biota-mediated soil functions. It supports the prospective sustainable use of sludge-based biochars. However, longer-term impact assessments on soil biota, and the influence of biochar ageing, on its ecotoxicological potential requires further investigation.

Activated carbons prepared from plum, apricot and cherry kernels: Influence of operational parameters and elemental composition on the maximum adsorption capacity of products

M. Turk-Sekulic, University of Novi Sad / Department of Environmental Engineering and Occupational Safety and Health; S. Pap, M. Brboric, M. Vojinovic Miloradov, University of Novi Sad Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; M. Prica, University of Novi Sad Faculty of Technical Sciences / Department of Graphic Engineering and Design; Z. Djukic, University of Novi Sad Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; J. Radonic, Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health

The use of alternative activated carbon derived from biomass, as agricultural waste material, has been investigated as a replacement for the current expensive methods of removing heavy metals from wastewater. The present investigation was undertaken to evaluate the adsorption effectiveness of plum, apricot and cherry kernels-based granular activated carbonsin removing Pb^{2+} ions commonly found in municipal and industrial wastewater. The primary source of biomass for the production of eco-friendly and low-cost biosorbents were lignocellulosic raw materials (fruit pits), as waste byproducts of the fruit industry and elements of organic municipal waste. Shells were activated by thermochemical conversion with phosphoric (H_3PO_4) and sulphuric (H_2SO_4) acid at 400°C and 500°C for 2 h, in the complete absence of nitrogen inert atmosphere. In the study, various parameters such as the impregnation type, activation temperature and elemental composition of kernels were evaluated to establish the separation efficiency of the Pb^{2+} ions in the optimum batch operational system mode. It was observed that theoperational parameters and composition of row materials have significant influence, in the range of 25.02 mg g^{-1} to 119.64 mg g^{-1}, on the maximum adsorption capacities of the synthesized activated carbons. The adsorbent derived from these materials is expected to be an economical product for metal ion remediation from wastewater. **Acknowledgement:** Ministry of Education, Science

and Technological Development, Republic of Serbia (III46009) has financially supported this research.

Effects of activated carbon on PCB bioaccumulation and biological responses of Chironomus riparius

I. Nybom; S. Abel, University of Eastern Finland / Department of Biology; G.C. Waissi-Leinonen, University of Eastern Finland; K. Vaananen, University of Eastern Finland / Biology; K. Maenpaa, University of Eastern Finland / Department of Biology; M.T. Leppanen, Finnish Environment Institute; J.V. Kukkonen, University of Jyvaskyla / Biological and Environmental Science; J. Akkanen, University of Eastern Finland / Biology

Activated carbon (AC) amendments have been studied as a new stabilizing method for contaminated sediments. The sorbtion efficiency of AC toward hydrophobic organic compounds (HOCs) has been shown in several studies. Recently the focus has been turned also to the possible secondary effects of AC amendments. At the present study the sorbtion efficiency and possible secondary effects of AC were studied with *Chironomus riparius* in a full life cycle test. Coal based AC (ø 63-200 μm) was mixed in natural sediments from PCB contaminated area. AC amendment reduced the PCB concentrations determined with both bioaccumulation test and passive samplers. Additionally the PCB concentrations of midges emerging from AC treated sediments were reduced. Adverse effects were observed on the larvae growth and development, and morphological changes were seen on the gut wall microvilli layer. On the other hand, low dose of AC (0.5% sediment dw) slightly improved reproduction, survival, larvae growth and gut wall microvilli length in one of the studied sediments, indicating that AC amendment reduced the sediment toxicity by altering the bioavailability of the contaminants. Site specific characteristics are important when the remedial measures are designed to be balance between effective contaminant bioavailability reduction and adverse effects of the amendments.

WE023

Influence of surface composition on removal of emerging contaminants from wastewater using carbonized agricultural residues

E. Weidemann, M. Niinipuu, J. Fick, S. Jansson, Umea University / Department of Chemistry

Clean water is a necessity for life and influences health, politics and human rights. The aim of this screening study was to assess the influence of the surface composition in the adsorption capacity of carbonized materials on ten environmentally occurring and relevant water pollutants, selected for their ability to pass unreduced through STP plants. Four wastes, horse manure, tomato residues, olive pressing residues, and rice husks were carbonized using hydrothermal carbonization (HTC). HTC is a wet carbonization process conducted in water phase, under pressure and at temperatures of 220-280 °C. A 10 µg/l model wastewater containing Ochtilinone, Triclosan (biocides), Trimethoprim, Sulfamethoxasole, Ciprofloxacin (antibiotics), Diclofenac, Paracetamol, Diphenhydramine, Fluconazole (pharmaceuticals), and Bisphenol A (plasticizer) in milliQ water were used for the adsorption tests. For the adsorption test triplicates, 10 ml of the model wastewater were added to 50 mg char in 15 ml plastic tubes, which were agitated for the adsorption time (1, 3, 5, 8, 12, 18 and 25 minutes at 20 °C). The removal efficiency differed between the four biochars, with horse manure and rice husks being the most efficient, with 68% and 74% average adsorption respectively after 25 minutes. Adsorption rates were fast, with high adsorption achieved already at the first sampling time. The adsorption efficiencies correlated somewhat with the water/octanol partitioning coefficient of the substances in the model water, but not at all with the water solubility. This did not explain why the manure char was almost as good adsorbent as the rice husk char, as it only had one fourth of the surface area (4 m^2/g compared to 16 m^2/g) To further investigate the differences in adsorption capacity of the chars, the surface composition of the chars was analyzed using diffuse reflectance furrier transform infrared spectroscopy (DRIFTS) and X-ray Photoelectron Spectroscopy (XPS). The result shows a large difference in surface composition between the chars which could hold the key to the different adsorption capacities. The Identification of a low-cost feedstock that enables capture of these emerging substances could improve water treatment both in global north (as an extra step in sewage treatment plants) and global south (e.g. as rudimental water filters) to improve the human and animal welfare as well as the environmental situation.

WE024

Carbon nanotubes as an effective adsorbent for Ionic Liquids removal

J. Maszkowska, University of Bremen / Center for Environmental Research and Sustainable Technology; J. Wojslawski, A. Bialk-Bielinska, M. Paszkiewicz, University of Gdansk / Department of Environmental Analysis Faculty of Chemistry; P. Stepnowski, University of Gdansk / Department of Environmental Analysis

For 20 years, many scientific publications have reported the presence of new compounds in the environment – emerging pollutants (EPs). However the largest challenge in the management of EPs is identification of the chemical substances which potentially can become dangerous in the future. Therefore, in spite of the mentioned group of contaminants, another important class of pollutants can be distinguished – potential pollutants (PPs), whose occurrence in the environment has not been documented yet but such probability is high nevertheless. Due to their unique properties (e.g. thermal stability, insignificantly negligible volatility, non-flammability, miscibility with water or other solvents) ionic liquids (ILs) are videly used in in a variety of industrial processes nowadays. Therefore a danger of possible contamination of the environment by these compounds is highly probable, and hence they can be considered as PPs. The lack of fresh and clean water is an ubiquitous problem around the world. Water demand is growing rapidly as a result of increasing population and rapid urbanization. Although activated carbon (AC) is one of the most widely used adsorbents in water treatment, its application also suffers from several bottlenecks, such as slow adsorption kinetics and difficulty for regeneration. Therefore, identifying alternative materials to AC is a key issue for tertiary treatments to remove xenobiotics from WWTP effluent and further research is required with respect to the design and preparation of novel absorbents with good sorption and regeneration properties. The aim of this work was to investigate interaction mechanism between different carbon nanotubes (CNTs) and selected ILs and asses whether they may be effective adsorbents for the ILs removal from wastewater or not. The strength and extent of the sorption phenomena were determined by sorption isotherms and sorption coefficients. All the results were modelled by Freundlich and Langmuir isotherms. Obtained results show that CNTs can be considered as superior to ACs in terms of sorption kinetics. Moreover sorption of ILs on CNTs is highly effective process. The sorption mechanism has been proposed. *Acknowledgement „Program rozwoju Uniwersytetu Gdanskiego w obszarach Europa 2020 (UG2020)" project is co-financed by the European Union under the European Social Fund.*

Remediation of PCB contaminated sediments using activated carbon: Assessing efficiency and robustness using equilibrium sampling

S.N. Schmidt, Technical University of Denmark / Department of Environmental Engineering; T.S. Bridges, US Army Engineer Research and Development Center; P.T. Gidley, US Army Engineer Research and Development Center / Engineer Research and Development Center; G.R. Lotufo, C.E. Ruiz, US Army Engineer Research and Development Center; A.J. Kennedy, US Army Engineer Research and Development Center / Environmental Laboratory; N.S. Rogers, US Army Engineer Research and Development Center; U. Ghosh, University of Maryland Baltimore County / Chemical Biochemical and Environmental Engineering; R.M. Burgess, U.S. EPA / Atlantic Ecology Division; L.A. Fernandez, Northeastern University / Quantitative Landscape Ecology; P. Mayer, Technical University of Denmark / Department of Environmental Engineering

When released into aquatic environments, polychlorinated biphenyls (PCBs) accumulate in sediments due to their low water solubility and association with sediment organic carbon. PCB contaminated sediments have been successfully remediated using activated carbon (AC) amendments, which strongly adsorb lipophilic compounds and thereby reduce their exposure/risk to benthic and pelagic organisms. For such remediation methods, it is important to carefully assess both the method efficiency in reducing exposure and the method robustness towards ongoing influx of contamination. In the present study, a series of mesocosm experiments were performed in order to reveal how AC amendments can be most effectively applied to reduce exposure and enhance the resilience of *in situ* sediment remedies challenged by ongoing influx of contamination. In these mesocosm experiments, contaminated sediments were (i) amended with activated carbon, (ii) covered by a sand cap, (iii) covered by an AC amended sand cap, and (iv) covered by a mobile AC amended sand cap. Half of the mesocosms received ongoing influx of contamination during the 3-months experiments. Careful exposure assessments were conducted before and after treatment in order to reveal how AC amendments can be most effectively applied in sediment remediation. As part of the exposure assessments, equilibrium sampling of the sediments were used to determine: (1) the freely dissolved PCB concentrations in sediment pore water (C_{free}, pmol/L), (2) the PCB chemical activities in sediment (a, unitless), and (3) the PCB concentrations in lipid at thermodynamic equilibrium with sediment ($C_{lipid \leftrightarrow sediment}$, mmol/kg). The freely dissolved concentration is frequently perceived as the effective concentration for bioconcentration and toxicity, while chemical activity (a medium-independent exposure parameter that quantifies the energetic level, and not the concentration, of an organic compound relative to its energetic level in pure liquid [0-1, unitless]) governs diffusion and equilibrium partitioning. Both freely dissolved concentrations and chemical activities express the effective exposure as opposed to the more traditionally used measure of total concentration. Still, the main novelty of this approach is that $C_{lipid \leftrightarrow sediment}$ can be determined in a practical and precise manner to express the thermodynamic potential for bioaccumulation (i.e. the concentration in the lipid of an organism at thermodynamic equilibrium with sediment).

WE026

Effects of biochar on the dynamic of metals in soils polluted by mining wastes under changing hydric conditions

J. Álvarez-Rogel, J. Sánchez Martínez, M. Tercero Gómez, H. Conesa Alcaraz, I. Párraga-Aguado, Escuela Técnica Superior de Ingeniería Agronómica. Universidad Politécnica de Cartagena / Ciencia y Tecnología Agraria; M.

González-Alcaraz, Faculty of Earth and Life Sciences, VU University / Ecological Science

The aim of the present study was to assess the effects of biochar and the presence/absence of vegetation on the fate of metals in wetland soils polluted by metal mining wastes to ascertain the effectiveness of these techniques on the improvment of soil conditions and the reduction of the environmental risks associated to metal pollution. A column (15 x 30 cm) experiment with two types of soils (one with pH~4.7 and another one with pH~7.4), two types of biochar (one from municipal solid wastes -MSW- and another one from sewage sludge -SS-) and with the presence/absence of plants (halophyte species *Sarcocornia fruticosa*) was performed with alternating flooding-drying conditions inside a greenhouse. The water level was kept at 5 cm above the soil surface for one month and at 15 cm below the soil surface for the following month. This cycle was repeated several times along the experiment. The pH and redox potential (Eh) were regularly checked as well as the dissolved organic carbon (DOC) and soluble metal concentrations (Cd, Mn, Pn and Zn) in pore water. In the basic soil the biochar application did not have any effect on soil pH. In the acidic soil the MSW biochar increased the pH from ~4.5 to 6.0-6.5 while the SS biochar to ~5.5. The presence of vegetation did not have any effect on soil pH. The SS biochar greatly decreased the Eh values in both study soils due to a higher input of DOC and then probably to a greater microbial activity. In the acidic soil the higher pH due to biochar application led to a decrease in the soluble metal concentrations regardless the Eh values and the presence/absence of plants. In the basic soil the drop of Eh values due to the flooding conditions favoured higher soluble Mn and Zn concentrations probably due to the solubilisation of metal oxides. The MSW biochar favoured higher soluble Cd concentrations after one month of flooding although the concentrations decreased when decreasing the water level. The dynamic of Pb was similar among all the treatments assayed, regardless the biochar and the presence/absence of plants, and was conditioned by the flooding regime. The Pb concentrations in pore water increased during the flooding periods and decreased during the drying ones probably due to the metal immobilisation/mobilisation in relation to the dynamic of sulfurs. The effectiveness of the treatments assayed (biochar application) depended on the soil type, the hydric regime and the presence/absence of vegetation.

Passive sampling of organic micropollutants and toxicity assessment: opportunities, challenges and innovations (P)

Bioaccumulation of hydrophobic organic contaminants in mussels in the Istanbul Strait: Field monitoring by means of passive water sampling and modelling

S.D. Yakan Dündar, Istanbul Technical University / Faculty of Naval Architecture and Ocean Engineering; A. Focks, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team

Determination of the concentrations of hydrophobic organic contaminants (HOCs) such as PAHs (polycyclic aromatic hydrocarbons) and PCBs (polychlorinated biphenyls) from water samples is difficult due to the low water solubility, high lipophilicity, strong adsorption tendency to suspended materials and tendency to accumulate in organisms. Biomonitoring and passive sampling methods are alternative ways of assessing the sources and fate of HOCs in the marine environment. Bivalve molluscs and Semi-Permeable Membrane Devices (SPMDs) are widely used in monitoring studies to collect information about water concentrations of HOCs. The simultaneous consideration of concentration data of bivalves and SPMDs enables conclusions about accumulation of HOCs in bivalves, even without information about water concentrations, because of their similar uptake processes. In this study, field monitoring data from the Istanbul Straitispresented. The Istanbul Strait is a busy route for both national and international navigation and hence has high potential for contamination. Specimens of the Mediterranean mussel species *Mytilus galloprovincialis* were deployed and stayed together with SPMDs in the water column for up to 21 days. A published model was adapted and used to calculate depuration rate constants and bioaccumulation factors for the mussel and a series of PAH and PCBs. Model interpolations based on separate PAH and PCB data match the trend in the data well, model interpolation using a hyperbolic fit of BAF factors show an inverse trend as compared to the single-substance models. Elimination rate constants are decreasing with Log K_{OW}>6 values and can be fitted best by a hyperbolic function for the combined PAH and PCB data. In conclusion, bioaccumulation and depuration kinetics of HOCs in *M. galloprovincialis* can be modelled properly based on Log $K_{OW.}$ While depuration constants show a clear hyperbolic trend, for the bioaccumulation factor's dependency on Log K_{OW},it is notcompletely clear whether linear or hyperbolic regression fits best. Using the hyperbolic regression equation in interpolation of SPMD/mussel concentration ratios (C_S/C_M), results in a completely switched response of C_S/C_M ratios for changing Log K_{OW}. Inclusion of more HOCs in monitoring studies will help to further investigation of this relation. Differences in the C_S/C_M ratios for different exposure durations can be modelled, and the duration of future monitoring experiments can be decided effectively.

Calibration of Polar Organic Chemical Integrative Sampler (POCIS) in wastewater treatment plant, and pesticide monitoring in wastewater network

V. Dufour, EPOC - UMR 5805 CNRS / UMR EPOC LPTC; D. Granger, M. Capdeville, LyRE - SUEZ; J. Cruz, K. Le Menach, P. Pardon, University of Bordeaux / UMR EPOC LPTC; N. Pouly, Bordeaux Metropole; B. Barillon, CIRSEE - SUEZ; M. Chambolle, LyRE - SUEZ; H. Budzinski, University of Bordeaux / UMR EPOC LPTC

Because of generalized uses of pesticides by agriculture, private consumers, industries or public authorities, pesticides are released into the environment, potentially affecting ecosystems. Reduction at source can be considered for some compounds. Wastewater via wastewater treatment plants (WWTP) have shown to be an important source of pesticides to the environment. Wastewaters are specific matrices, difficult to monitor and heterogeneous, with high amount of organic matter, variable water depths and high variability of pesticide concentrations. All these drawbacks can compromise the regular sampling of wastewater, so passive sampling seems to be a good alternative to high frequency grab sampling for pesticide monitoring. This study evaluated the potential of Polar Organic Chemical Integrative Sampler (POCIS) as medium term samplers. POCIS were calibrated *in-situ*, in a WWTP influent, and on a small peri-urban river, generating sampling rates for a large amount of pesticides. Some POCIS were also deployed on wastewater network and in the river for short term monitoring of pesticides, conducing to calculation of time weighted average concentrations. These experiments brought to light that the time of exposure in wastewater was short (about 3 days) for a quantitative purpose. Moreover the devices appeared to be not so appropriate in such environments due to solids that have been accumulated on them, and could have led to wrong estimation of time weighted average concentrations in wastewater. New designs of the sampler were tested in lab and on field to improve the sampling capacity of this dispositive. A better knowledge of the contamination of micropollutants in wastewater can lead to the identification of sources in wastewater network, reducing contamination at source, in the perspective of protecting water resources. *Acknowledgement* - This study benefited from funds in relation with RESEAU and "Plan Micropolluants" projects (associating as partners: Bordeaux Métropole, SUEZ, IRSTEA, Water Agency, CNRS, University of Bordeaux, CHU and Aquitaine Regional Council). This work was funded by the Aquitaine Regional Council and SUEZ. This study has been carried out with financial support from the French National Research Agency (ANR) in the frame on the Investments for the future programme, within the Cluster of Excellence COTE (ANR-10-LABX-45)

Effects of Flow Conditions on POCIS Sampling Rate for Constant Pesticides Concentration Exposures

V. Toteu Djomte, Baylor University / Chemistry Biochemistry; B. Dhungana, Baylor University / Chemistry and Biochemistry; K. Chambliss, Baylor University / Department of Chemistry

The effects of hydrodynamic conditions on polar organic chemical integrative sampler (POCIS) uptake rates for a range of pesticides were investigated in a controlled laboratory setting. The POCIS devices were exposed to constant concentrations of pesticides under different flow conditions (static, 1 $cm.s^{-1}$, 3 $cm.s^{-1}$, 4 $cm.s^{-1}$ and 5 $cm.s^{-1}$) over a period of 20 days. The results showed that for most compounds, there was an increase (up to more than one order of magnitude) of sampling rate with increasing flow velocity. However, this trend was slightly different for the neonicotinoid thiamethoxam, where a lower sampling rate was observed at 5 $cm.s^{-1}$ compared to flow conditions of 1, 3 and 4 $cm.s^{-1}$. Generally, a positive correlation was observed between the sampling rates and hydrophobicity (log octanol/water partition coefficient, log K_{OW}) for pesticides with log K_{OW} ranging from 1 to 3. Study results also include the first reported estimates of POCIS sampling rates for bicyclopyrone and cyproconazole.

WE030

Passive sampling: A viable technique for post registration monitoring? A review.

N. Brettell, T. Pepper, ADAS UK Ltd / Cambridge Environmental Assessments; S. Taylor, Cambridge Environmental Assessments; L. Fogg, ADAS UK Ltd / Cambridge Environmental Assessments

Passive sampling techniques have been developed and successfully deployed for monitoring pesticides in surface, ground and marine waters, as well as air sampling and sampling for bystander exposure. To date, passive sampling has not been recognised as a method suitable for data collection within regulatory studies, possibly due to uncertainties involved with the extensive calibration procedures and matrix selection usually required. However, with the extended provision for post registration monitoring of pesticides under the current pesticide Regulation (Regulation (EC) No. 1107/2009), passive sampling may provide a cost effective alternative to conventional sampling techniques. Although no specific guidance on the use of passive samplers for pesticide monitoring in the regulatory context currently exists under Regulation (EC) No. 1107/2009, use is mentioned in Directive 2013/39/EU "Priority Substances", stating; "novel monitoring methods such as passive sampling and other tools show promise for future application, and their development should therefore be pursued". Additionally, although not directly referred to in Directive 2000/60/EC "The Water Framework Directive", passive sampling is listed as a complementary sampling method within the WFD guidance document, stating that "passive sampling can be used alongside spot sampling to confirm or refute the results of spot sampling". This review will consider current developments in passive sampling technology in relation to monitoring pesticides, and their relevance in relation to data submission for regulatory requirements.

WE031

Pesticide quantification in POCIS extracts: matrix effect due to polymers in polyethersulfone membranes and washing protocol

R. Guibal, S. Lissalde, A. Charriau, G. Guibaud, University of Limoges / Research Group on Water Soil and Environment GRESE

Passive samplers are exposed in the aquatic environment for some days and a time-weighted average concentration (TWAC) can be calculated which improves the representativeness of pollutant concentration, compared to punctual sampling. For pesticide residues, the Polar Organic Chemical Integrative Sampler (POCIS) prepared from a sorbent material (Oasis HLB) enclosed between two polyethersulfone (PES) membranes can be used. To mitigate the effects of environmental parameters (fouling, variations in flow velocity), performance and reference compounds (PRC) are applied. The presence of polyethylene glycol compounds (PEG) released by PES membranes in POCIS extracts was shown by high resolution time-of-flight mass spectrometry. PEG compounds induce strong matrix effects during PRC and target molecule quantification. Dilution of POCIS extracts can reduce this matrix effect but decreases POCIS performance (quantification limit). As confidence in quantification is the key to a satisfactory interpretation of environmental contamination, this work aimed at investigating the effect of analytical interferences on pesticide and PRC quantification and also proposing a washing protocol for PES membranes [1]. To study interferences, a matrix collected from POCIS exposed in freshwater was used. POCIS extracts were diluted at different levels (1/10; 1/25) and spiked with a pesticide mixture (from 10 $\mu g.L^{-1}$ to 100 $\mu g.L^{-1}$). A suppression of DIA-d5 signal (deisopropylatrazine) was induced by interferences. As this substance is used as a PRC, the quantification bias hamper the TWACs calculated for the other pesticides. A washing procedure consisting of two successive baths with ultra pure water (UPW) / methanol (50/50) and a final rinse with UPW was proposed to limit PEG release. Total ion current chromatograms of extracts from POCIS built with washed PES membranes did not display a significant PEG fingerprint. The removal of PEG interference allows proper quantification of DIA-d5 and pesticides during the PEG retention time range (3.5 – 5.5 min) with a 10-time dilution. With a slight extract dilution (10 instead of 25 times for POCIS with unwashed membranes), pesticides at very low concentration can be properly detected and quantified which further improves the ability of POCIS to quantify molecules at very low content in water, particularly those eluting with PEG contaminants. WE032

Sorption of structurally different ionized pharmaceutical and illicit drugs to a mixed-mode coated microsampler

s. droge, Utrecht University / IRAS; H. Peltenburg, N. Timmer, J. Hermens, Utrecht University / Institute for Risk Assessment Sciences

The mixed-mode (C18/strong cation exchange-SCX) solid-phase microextraction (SPME) fiber has increased sensitivity for ionic compounds compared to more conventional sampler coatings such as PDMS and polyacrylate. However, data for structurally diverse compounds to this sampler coating are too limited to define structural limitations of this type of passive sampler. We determined C18/SCX fiber partitioning coefficients of 17 cationic structures without hydrogen bonding capacity besides the charged group, stretching over a wide hydrophobicity range, and 8 strongly basic pharmaceutical and illicit drugs with additional hydrogen bonding moieties. In addition, several neutral benzodiazepines and the acid diclofenac were tested. All tested compounds showed nonlinear isotherms above 1 mmol/L coating, and linear isotherms below 1 mmol/L. The affinity for C18/SCX-SPME for tested organic cations without H-bond capacities increased with longer alkyl chains, ranging from log$D_{\text{fiber-water}}$ 1.8 (benzylamine) and 5.8 (triflupromazine). Smaller amines than benzylamine may thus have limited detection levels, and cationic surfactants with alkyl chain lengths >12 carbon atoms may sorb too strong to the C18-SCX sampler which hampers calibration of the fiber-water relationship. The logD_{fw} for these simple cation structures closely correlates with molecular volume and the octanol-water partition coefficient of the neutral form ($K_{\text{OW,N}}$). Oxygen moieties in organic cations decreased the affinity to C18/SCX-SPME, in comparison to the relationship with molecular volume established with the simple cationic structures, within a factor of 3 of the $K_{\text{OW,N}}$ relationship for simple cations, and only for 2/8 of these polar cations to a more than 10 times lesser extent than predicted by $K_{\text{OW,N}}$. Neutral benzodiazepines sorbed a log unit stronger than their $K_{\text{OW,N}}$. Results for anionic diclofenac species ($K_{\text{OW,N}}$ 4.5, pKa 4.0, log$D_{\text{fw,pH7.4}}$ 2.9) indicate that C18-SCX, despite the negatively charged SCX moieties, may even be useful for sampling a wide range of other dissociated carboxylic acid structures (surfactants, pharmaceuticals) and other types of organic anions (sulfates, sulfonates) that are notoriously difficult to sample with bulk polymer phase coated samplers. This data demonstrates the applicability of C18-based SPME in the measurement of freely dissolved concentrations of a wide range of ionizable compounds in many types of environmental and pharmacological studies.

WE033

Equilibrium sampling in a semi in situ pot experiment to measure freely dissolved concentrations of hydrophobic organic compounds.

N. Bartolomé, Agroscope ISS / Analytical Chemistry Natural Resources Environmental Protection in Agriculture; I. Hilber, Agroscope ART; R. Schulin, Institute of Environmental Engineering ETH Zurich / Department of Environmental System Science; P. Mayer, Technical University of Denmark / Department of Environmental Engineering; G. Witt, HAW Hamburg / Department of Environmental Engineering; T. Bucheli, Agroscope ART / Environmental Analytics Natural Resources and Agriculture

Progress has been made to develop and apply *in situ* passive sampling techniques for sensing hydrophobic organic contaminants (HOC) in the field, mainly in air, water and sediments. However, there is very little information on the capability of these methods to assess the bioavailability of HOC in soil. Under field conditions, environmental factors such as temperature, ionic strength or water content may influence the phase distribution of HOCs. Conducting passive sampling of HOCs *in situ* has the advantage of taking these actual environmental conditions automatically into account, in contrast to standard laboratory tests, which are performed under saturated water conditions (i.e. in suspensions). Here, we present an *in situ* pot experiment to assess bioavailability of polycyclic aromatic hydrocarbons (PAHs) in a historically contaminated soil with two different passive sampling techniques: low density polyethylene (LDPE) [1] and polydimethylsiloxane (PDMS) glass fibers [2]. The objective of this study is to investigate the concordance of the passive samplers, with the more widely used *ex situ* laboratory method using soil suspensions. Soil was excavated from the upper 20cm of a pigeon shooting range in Embrach, Switzerland, which was contaminated with 270 mg/kg total concentration of the sum of the 16EPA PAHs. The soil was thoroughly mixed according to Bucheli et al. [3], and the samplers were deployed directly into the pots with 1.5 kg soil and put into the greenhouse. The samplers were exposed for 3, 6 and 9 months. Some pots were kept at 60% water saturation, which is close to field capacity, and others at full 100% saturation. Results of the two passive samplers from both experiments will be presented and correlated to each other, and the outcomes will be compared to PAH bioaccumulation by earthworms and plants also derived from the very same pot experiment. This research will help to evaluate the applicability of these passive samplers directly *in situ* under soil unsaturated field conditions.

Soil-atmosphere exchange of persistent organic pollutants: Determination of concentration gradients with passive samplers

J. Meierdierks, Hydrogeochemistry; C. Zarfl, University of Tuebingen / Center for Applied Geosciences; P. Grathwohl, Eberhard Karls Universität Tübingen / Center for Applied Geosciences

Since the last century soils have accumulated plenty of anthropogenic chemicals like the persistent organic pollutants (POPs) which might revolatilize due to decreasing atmospheric concentrations during recent decades. As a contaminant class within the group of POPs the polycyclic aromatic hydrocarbons (PAHs) feature characteristic properties as probable human carcinogens with relatively high concentrations in surface soils, allowing accurate measurements of concentration gradients, and are therefore a relevant class of chemicals of concern. The direction and magnitude of diffusive contaminant flux across the soil–air interface is controlled by the gradient of gas-phase concentration. Past investigations into the soil–air exchange of contaminants have relied on estimation methods for calculating contaminant fugacity in soil because appropriate methodologies for measuring these gradients are not available. This study aims to overcome these problems by using time-integrating passive samplers to determine concentration gradients in the soil and across the soil–atmosphere interface. Passive samplers circumvent the need of estimating a contaminant's soil partitioning properties by acting directly as a sensor for contaminant activity (e.g. fugacity or availability) in environmental media. 80 μm thick low-density Polyethylene (LDPE) sheets spiked with performance reference compounds (PRC) were deployed in the field to sample atmospheric concentrations of PAHs. Deployments during summer, winter and spring were conducted to check on seasonal variations and correlations with climatic conditions. By comparing PAH concentrations within covered and uncovered sheets the impact of photodegradation on the accumulated PAHs was tested, which can be considered exclusively significant with respect to the PRC and depending on the season. Soil samples were taken at 5 intervals, up to 50 cm depths and equilibrated ex-situ with 30 μm thick LDPE sheets. Evaluation of concentration gradients in the soil, sorption/desorption behaviour of PAHs, as well as soil characteristics such as soil texture, porosity, water content and amount and type of organic matter was performed to verify further correlations with the exchange at the soil-atmosphere surface. The monitoring outcomes from the field and laboratory studies are used in the validation of a numerical model of soil-atmosphere exchange of persistent organic pollutants.

WE035
Calibration of PDMS and XAD-coated PDMS for measuring organophosphate flame-retardants (OPFRs) and perfluorinated compounds indoors
J.O. Okeme, University of Toronto / Physical and Environmental Sciences; A. Abdollahi, University of Toronto / Department of Earth Sciences; S. Dhal, University of Toronto / Dalla Lana School of Public Health; L.M. Jantunen, Environment Canada / Air Quality Processes Research Section Centre for Atmospheric Research Experiments; M.E. Shoeib, Environment Canada / Atmospheric Science and Technology Directorate; M.L. Diamond, University of Toronto / Department of Earth Sciences
Passive air samplers (PAS) are increasingly employed for monitoring semi-volatile organic compounds (SVOC) concentrations in the environment, although less work has been done on their use indoors. We report on passive air samplers consisting of polydimethylsiloxane (PDMS) and a newly designed PDMS coated with styrene divinyl benzene co-polymer (PDMS-XAD), in comparison to the popular polyurethane foam (PUF) with a single bowl shelter. An indoor air calibration study was conducted to determine passive sampling rates by deploying these PAS and comparing with air concentrations measured using two low-volume active air samplers analyzed for gas and particle phases separately. Analytes of interest are brominated and organophosphate flame retardants, phthalate esters and polycyclic aromatic hydrocarbons (PAHs) and perflourinated compounds. The study extended for 50 days. Surface-area normalized uptake rates of PDMS were comparable to PUF using the single bowl shelter, ranging between 0.6 to 1.5 m^3 day^{-1} dm^{-2} for brominated flame retardants and phthalates. Preliminary results showed that the number of target chemicals was increased with the PDMS-XAD design because of differences in chemical properties of PDMS and XAD.

WE036
Estimating Uncertainties in Air-Water Diffusive Exchange Flux and Gross Volatilization Loss of PCBs: a Case Study based on Passive Sampling in the Lower Great Lakes
Y. Liu; S. WANG, Tongji University / State Key Laboratory of Pollution Control and Resources Reuse; R. Lohmann, University of Rhode Island / Graduate School of Oceanography
Air-water diffusive exchange is a significant process in PCB geochemical cycling across the Great Lakes. Compared with dry and wet deposition fluxes, the diffusive flux cannot be directly measured experimentally. Its model-based calculation contained considerable uncertainty because of uncertainties in atmospheric and aqueous concentrations and meteorological conditions. To capture inherent variability of the diffusive flux and load of PCBs, 57 pairs of air and water samples from 19 sites covering the Lake Erie and Ontario were collected using passive sampling during 2011-2012. Error propagation analysis and Monte Carlo simulation (MCS) were applied to estimate uncertainty in the diffusive flux. Passive sampling technique can provide a more precise estimate on direction of air-water diffusive exchange of PCBs. Best-fit values of wind speed and temperature from probability distribution function can quantify more precisely the site-specific diffusive flux. We confirmed that 30-40% of relative uncertainty in overall mass transfer velocity was a reasonable and acceptable assumption in error propagation to a large extent. Results from error propagation analysis were comparable with those from MC simulation, but the former would not be recommended in net deposition situation. Parameters sensitivities were different in net deposition, volatilization and equilibrium situations. Volatilization flux of 7 PCBs with maximum frequency across Lake Erie and Ontario was 618 pg m^{-2} day^{-1} and 426 pg m^{-2} day^{-1}, respectively, and annual gross volatilization loss of 7 PCBs was 45.65 kg $year^{-1}$ for Lake Erie and 32.42 kg $year^{-1}$ for Lake Ontario in 2011-2012.

WE037
Persistent organic pollutants (POPs) at Ross Sea (Antarctica) and through Circumpolar Deep Water.
s. giannarelli, University of Pisa / Chemistry and Industrial Chemistry; R. Fuoco, S. Francesconi, University of Pisa / Dept of Chemistry and Industrial Chemistry
The Antarctic region is ideal place for environmental studies of the marine ecosystem both near the coastal line and off-shore, due to the almost total absence of local pollution sources. In fact, pollutants reach Antarctica almost exclusively by long range transport processes involving both the atmosphere and the hydrosphere. The Circumpolar Deep Water (CDW), the largest circulation feature of the Southern Ocean, is mainly responsible for the rather limited exchange processes between the Antarctic seas and the outer oceans, thus it may be a possible source of persistent organic pollutants (POPs). The most significant findings on the presence of POPs in the marine ecosystem at Ross Sea and on CDW circulation will be discussed. Seawater samples were collected in many sampling sites located in a large area of the Ross Sea and during the travel to and from Antarctica during the XXVIIth Italian expedition. Two classes of POPs are considered, namely polychlorobiphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs). Some data was also obtained on the mixing process between two important water masses present in the area of the Ross Sea under investigation: the Modified Circumpolar Deep Water (MCDW) and the High Salinity Shelf Water (HSSW). The MCDW, relatively warmer, comes from the external oceanic circulation in the Pacific sector of the Southern Ocean, whereas the HSSW, relatively colder, is generated inside the Ross Sea basin. Both move towards Cape Adere where they mix. The intrusion of MCDW in the colder HSSW is clearly evident: the very sharp change in the temperature at about 170m depth from -1.5 ºC (typical of the HSSW) to +0.2 ºC (typical of the MCDW) is in very good agreement with a sudden change in the PCB concentration by a factor of two. The same behaviour was also observed for the total content of PAHs. This is the first experimental evidence of the pollutant input in the Ross Sea basin from the external oceanic circulation, which happens in a period of the season when the ecosystem is particularly sensitive since the biological activity is at its peak.

WE038
Laboratory calibration of two passive samplers for aquatic organic contaminants: POCIS and a new mixed polymer sampler
Y. Jeong, KIST Europe; A. Schaeffer, K. Smith, RWTH Aachen University / Institute for Environmental Research
Uncertainty in the determination of the compound-specific sampling rates is a major issue leading to errors in the conversion of Polar Organic Chemical Integrative Sampler (POCIS) measurements into environmental dissolved concentration, and is one of the main challenges with kinetic passive sampling. The affinity of compound to the sorbent and membrane used for constructing POCIS, as well as the sampling rate, are all compound dependent. Therefore, it is important to better understand the uptake kinetics of such passive samplers aimed at sampling polar organic compounds. Furthermore, relating these uptake kinetics to the compound properties will allow the sampling rates of other compounds to be estimated when measurements are not available. Polydimethylsiloxane (PDMS) silicone is commonly used for the passive sampling of neutral hydrophobic organic compounds in aquatic environments. PDMS passive samplers are directly exposed to the surrounding aquatic environment, which maximizes accumulation but also simplifies the uptake process. Other advantages include reversible sorption, which is relevant when considering the application in passive dosing mode for toxicity test. Unfortunately, PDMS is not an ideal choice for polar organic compounds because of its lower partitioning affinity which leads to problems with analytical detection. The above issues raise the question whether it is possible to combine the advantageous properties of PDMS sampler with the higher affinity of a sorbent such as Oasis HLB to make a sampler for both polar and non-polar compounds. In this study, Oasis HLB were embedded within PDMS disks to make a mixed polymer sampler (MPS). MPS disks had a high affinity for both polar and non-polar hydrophobic organics and were much easier to handle since they consisted of a single polymer block. The uptake kinetics of a range of compounds from the aqueous phase to the MPS and the traditional POCIS were compared using a batch set-up. The sampling rate to each sampler was calculated by fitting a numerical model. Subsequently, the desorption of the compounds from the equilibrated samplers was measured. These measured uptake and desorption kinetics were related to the physico-chemical properties of the chemicals as well as the sampler architectures. Therefore, the MPS had a similar performance to the traditional POCIS which the advantage that it was easier to handle and can potentially be used for passive dosing in toxicity testing.

WE039
Investigating methods for in tissue equilibrium passive sampling of POPs in lean fish
F. Smedes, Masaryk University / RECETOX   Research centre for toxic compounds in the environment; P. Carlsson, T. Rusina, J. Sobotka, Masaryk University Faculty of Science RECETOX / Environmental chemistry and modelling; R. Kopp, Mendel University / Department of Fisheries and Hydrobiology; B. Vrana, Masaryk University, Faculty of Science, RECETOX / Environmental chemistry and modelling
Estimation of bioaccumulation factors (BAF) of hydrophobic substances requires measurement in aquatic biota as well as in the water phase at a steady state. Passive sampling is used extensively to quantify freely dissolved concentrations of persistent organic pollutants (POPs) in sediment pore water and surface water as a relevant parameter for the assessment of organism exposure. Furthermore, passive sampling can also be applied in fish tissue. Passive samplers that are equilibrated with water, sediment and fish would contain equal POP concentrations if the fish was at the state of a thermodynamic equilibrium with water and/or sediment. If concentrations were not equal the degree of disequilibrium would be revealed, which is equally important for bioaccumulation studies. The presently applied method for in tissue passive sampling is restricted to application for lipid rich fish tissues since the uptake capacity in lean fish of the sampler may easily exhaust the POPs from the tissue in contact with the sampler. That ultimately leads to an underestimation of the POPs concentration level in the tested tissue. We investigated several ways to solve this problem using specimen of lean fish (e.g. pike, *Esox lucius*) and more lipid-rich fish such as carp (*Cyprinus sp.*).

Equilibrium partitioning of PCBs and PBDEs between tissue and silicone rubber samplers was investigated by daily moving samplers to another position in the tissue to avoid depletion. Sampler movement was performed manually and done 4 times (4 days exposure in total). A parallel experiment was performed by rolling pieces of fish tissue together with passive samplers in a glass jar for 4 days. All incubations were done at 4°C. In all experiments the degree of equilibrium was monitored by quantifying the release of performance reference compounds (PRCs) dosed to the sampler prior to exposure. Data were compared with measurement of total POP concentration of analytes in tissue samples. Derived method figures of merit include the minimum exposure time to reach partition equilibrium for all investigated substances, its relationship to tissue lipid content, as well as a minimum mass of tissue required to reach quantification limits. This method has a large application potential for bioaccumulation studies, also for some emerging environmental contaminants.

WE040

Quantifying the effects of temperature and salinity on partitioning of hydrophobic organic chemicals to silicone rubber passive samplers

M.T. Jonker, Utrecht University; S. van der Heijden, Institute for Risk Assessment Sciences / Institute for Risk Assessment Sciences; M. Kotte, RWS; T. Hamers, Institute for Environmental Studies IVM VU University Amsterdam

Nowadays, passive sampling is a widely applied technique to determine freely dissolved aqueous concentrations of hydrophobic organic chemicals (HOCs), such as polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs). Crucial to the measurements are sampler-water partition coefficients, which are generally determined in the laboratory under 'standard conditions' (in freshwater at 20 °C). Theoretically, however, the coefficients are dependent on environmental conditions, such as temperature and salinity. Yet, there are insufficient experimental data in the scientific literature to prove this for different polymers. Several polymers are already being applied during field monitoring however, and neglecting any effects may lead to imprecise results. In the present study, we therefore quantified the effects of temperature and salinity on the sampler-water partition coefficients of PAHs and PCBs for silicone rubber, a material used in Dutch passive sampling monitoring campaigns. The results demonstrated a chemical-specific and hydrophobicity-dependent temperature effect, being independent of salinity; and a chemical- and temperature-independent salinity effect. Based on the obtained data, location-specific silicone rubber-water partition coefficients ($K_{sr\text{-}w}$; adjusted for temperature and salinity) can be calculated. The impact of applying such location-specific values was demonstrated using the Dutch passive sampling field monitoring database, covering ten-years of PAH and PCB data for several locations. Adjusting the $K_{sr\text{-}w}$ values resulted in aqueous concentrations that were lowered by a factor of 1.6 on average. The reduction was rather constant because of the manner of sampling (under non-equilibrium conditions and using performance reference compounds) and calculating. When sampling under equilibrium conditions in seawater at temperatures at about freezing, and/or applying different calculation approaches, the adjustment effect can potentially increase up to a factor of about 5-6 for the more hydrophobic PAHs and PCBs. Although this study exclusively focused on silicone rubber, qualitatively the results will also apply to other passive sampling materials.

WE041

Combining passive sampling and 'slow stirring' to determine octanol-water partition coefficients for extremely hydrophobic chemicals

M.T. Jonker, Utrecht University

Octanol-water partition coefficients (K_{ow}) are widely used in fate and effects modelling of chemicals. Still, high quality experimental K_{ow} data are scarce, in particular for very hydrophobic chemicals. This hampers reliable assessments of several fate and effect parameters and the development and validation of new models. One reason for the limited availability of experimental values may relate to the challenging nature of K_{ow} measurements. In the present study, K_{ow} values for 13 polycyclic aromatic hydrocarbons (PAHs) were determined with the gold standard 'slow stirring' method ($\log K_{ow}$ 4.6-7.2). These values were then used as reference data for the development of an alternative method for measuring K_{ow}. This approach combined slow stirring and equilibrium sampling of the extremely low aqueous concentrations with polydimethylsiloxane-coated solid phase micro extraction (SPME) fibers, applying experimentally-determined fiber-water partition coefficients. It resulted in K_{ow} values matching the slow stirring data very well. Therefore, the method was subsequently applied to a series of 17 moderately to extremely hydrophobic petrochemical compounds. The obtained K_{ow} values spanned almost 6 orders of magnitude, with the highest value measuring $10^{10.6}$. The present study thereby demonstrates that the hydrophobicity domain within which experimental K_{ow} measurements are possible can be extended with the help of SPME; and that experimentally-determined K_{ow} values can exceed the proposed upper limit of 10^9.

WE042

Passive sampling strategies to monitor Polycyclic Aromatic Hydrocarbon (PAH) emissions to rivers during base flow and flood waves

T. Gallé, Luxembourg Institute of Science and Technology (LIST) / ERIN; V. Lumbab, University of Trier / Dept of Hydrology; D. Pittois, A. Krein, Luxembourg Institute of Science and Technology LIST

Polycyclic aromatic hydrocarbons (PAH) remain an issue in the WFD due to very low EQS for higher molecular compounds of this group. Sources of PAH are often manifold reaching from street runoff to alluvial groundwater inputs from contaminated sites and the pollution pathways are dynamic. This confronts water managers with enormous challenges in investigative monitoring. We explored the use of two types of passives samplers to investigate the flow pathways and phase in which PAH are transported: Sediment nets are continuously collecting suspended matter in rivers and are low-tech enough to be able to perform longitudinal profiles with multiple sampling points in order to locate PAH sources. In the same time Empore discs are used to collect dissolved PAH from the water phase. The hypothesis was that – according to the source – in variable hydrological situations and source locations differences would be expected between particulate and dissolved collected PAH depending on pathway and freshness of the contamination. In order to test this hypothesis 3 locations with different sources in a longitudinal profile on a river have been chosen: 1) a site with urban emissions (combined sewer overflows) 2) a site with a tributary input from a large gas station 3) a site with a tributary with a WWTP input. Results showed that large hydrological events were dominated by erosion with background contamination of PAH and identical levels and relationships of particulate vs dissolved concentrations in the three sites. During low flow and smaller events differences between the sites were obvious especially in the Empore disc collected phase, showing the presence of freshly contaminated suspended matter (rapidly desorbing) or alluvial groundwater inputs at the gas station site. In general the apparent Koc for individual PAH calculated from suspended matter contents and time weighted average concentrations from Empore discs were two orders of magnitudes above he equilibrium Koc from the literature. This shows that pollution of particulate matter in rivers is often aged and equilibrium calculations for EQS evaluation can introduce great bias.

WE043

Evaluating pharmaceuticals in rivers as tracers for WWTP performance in whole catchments

T. Gallé, Luxembourg Institute of Science and Technology (LIST) / ERIN; R. Wang, University of Trier / Dept of Hydrology; M. Bayerle, D. Pittois, Luxembourg Institute of Science and Technology LIST

Pharmaceuticals display variable fate in waste water treatment, but also following emission to rivers. Some compounds like carbamazepine can be used as a conservative tracer and can be directly related to population equivalents emitted in a river catchment. Other compounds reflect the performance of treatment plants and their presence in rivers can be used to evaluate the overall degradation efficiency in a river catchment. This requires the in-river fate of the compounds to be quantifiable: Indeed some compounds are subject to photodegradation or microbial transformation during transport in a river. Here we investigate the fate of a dozen pharmaceuticals using 1) diel autosampler campaigns to evaluate photochemical degradation and 2) longitudinal profiles with passive samplers and grab samples to evaluate overall mitigation over a stretch of 12 km downstream a major waste water treatment plant in Luxembourg. Grab sample profiles are prone to errors due to potential pollution peaks whose travel time cannot be considered in longitudinal profiles. Passive samplers overcome this problem by averaging over 14 days. In addition the comparison of passive sampling and grab sampling longitudinal profiles provides insight in the mitigation process: grab samples reflect mostly day-time processes while passive samplers cover the night period too. Hence, different mitigation rates indicate the photodegradation to be relevant. Three campaigns in series have been conducted and confirmed the feasibility of the concept although non-constant performance of the WWTP and the mid-term occurrence of a sewer discharge in the longitudinal profile reduced the pertinence of the data.

WE044

Application of passive sampling technique for monitoring 64 pesticides in Japanese surface water

Y. Kameda, Chiba Institute of Technology / Civil Architectural and Environmental Engineering

To monitor various pesticides in surface water is very important in an aquatic environment. Especially, continuous or frequent monitoring is desirable in the source of water supply. In Japan, there are several hundred species of pesticides to monitor in surface river water as well as purified water in order to supply "safe" drinking water. However, not all the pesticides are investigated at most rivers and lakes for drinking water. Furthermore, their water samples are generally collected once a month though a large amount of herbicides are spread over paddy fields in every spring and summer. Therefore, novel monitoring techniques are needed for simultaneous analysis and continuous monitoring for a variety of pesticides in surface water. Passive sampling technique is one of the possible monitoring methods, which can estimate time-weighted average concentrations (TWA) and can accumulate concentration data during sampler deployment. In this study, passive sampling technique was developed to monitor 64 pesticides mainly used for paddy field. Empore SDB-XD disks were used for absorbent and put them into Chemcatcher® holders. Calibration experiments using flow-through exposure systems were conducted in order to reveal sampling rates for 64 pesticides in our laboratory. Absorbed mass of 64 pesticides were analyzed by GC/MS. The calibration tests were performed under four different conditions of water velocity. Some chemicals like isotopically aromatic hydrocarbons were added as performance reference compounds and flow monitors. We also applied this passive sampling technique to some rivers and revealed seasonal trends of 64 pesticides TWA and compared TWA and grab sampling data.

Developing ceramic passive samplers to monitor cytostatic drugs in river water

H. Franquet, Environmental Chemistry; V. Pueyo, IDAEA-CSIC; J. Silva, V. Orera, ICMA-CSIC; S. Lacorte, IDAEA-CSIC / Environmental Chemistry

Cytostatic drugs have recently been detected in river waters as a result of its high and increasing consumption, becoming new water contaminants. Currently, grab sampling is the most common way to collect samples from rivers although it might not be completely representative of the river quality due to time dependant variability. In a previous study, grab sampling monitoring was performed in a drinking water treatment plant (DWTP) and along the Besòs River (near Barcelona, Catalonia, NE Spain). In the DWTP intake, mycophenolic acid was detected at concentrations between 17 to 52 ng L^{-1}. In the Besòs River, two sampling campaigns were performed and different concentration profiles were obtained along the river for 14 cytostatic drugs, showing that their emission to the waters is reiterative but with high concentration variability. Therefore, passive samplers can be used to better evaluate the presence of cytostatic drugs in the aquatic environment, as they can be efficient, relative inexpensive and provide time integrated concentrations. Ceramic passive samplers had been developed, using porous ceramic tubes (45 mm x 13 mm, ID 9 mm) and 200 mg Zepra ZT (30 μm, 85 Å, Phenomenex) adsorbent. The adsorbent was conditioned with MeOH and water, and the tubes were filled. If needed, more water was added to completely fill the internal volume in order to facilitate the drugs diffusion. Then, they were kept in milli-Q water until deployment. For laboratory test, 10 devices were immersed in a 4L solution containing a mixture of 16 cytostatic drugs at 20 μg L^{-1}. They were deployed from 2 to 11 days to evaluate their adsorption, and two samplers were removed every 2 days. The adsorbent was removed from the tube and was extracted using MeOH in an ultrasonic bath. Linear adsorption was observed for most of the drugs, being up to 200 ng after 11 days, which allowed calculating the diffusion coefficients and the sampling rates. Then, 6 devices were deployed in the DWTP intake during 1 to 3 weeks to see the fouling effect. Finally, the passive samplers were deployed in the DWTP intake and in the Besòs River.

WE046

Passive sampling technique combined with ELISA assay detection for monitoring neonicotinoid insecticides in Japanese surface water

Y. Kameda, Chiba Institute of Technology / Civil Architectural and Environmental Engineering

Neonicotinoid insecticides are widely used in Japan. Especially, seven neonicotinoid insecticides such as Imidacloprid, Acetamiprid, Thiocloprid, Clothianidin, Dinotefuran, Thiamethoxam and Nitenpyram are popular. Their usage began from the beginning of 1990 and is increasing till 2008 in Japan. Recent annual total usage of seven insecticides is not increasing, approximately 400 tons per year in Japan. However very little is known about their occurrence, their behaviors and their ecological risk in Japan. Although their monitoring in surface water including storm water, wastewater and sewage treated water, which can be important to Japanese aquatic environment, is necessary to their ecological risk assessment, two big problems must be solved. One problem is their difficult analytical method by using LC/MS/MS. The other is their monitoring method which is constituted by only grab sampling. Grab sampling is a very basic and effective sampling method when the “sampling frequency” is high. However, high frequency is difficult in most investigations and screenings. In this study, a novel monitoring method to measure neonicotinoid insecticides in surface water is developed. This method is constituted of two techniques, passive sampling technique and ELISA assay detection technique. Passive sampling technique is very useful to on-site concentration, accumulation monitoring during deployment and evaluating time-weighted average concentration. ELISA assay detection is very simple, rapid, selective and sensitive determination technique. In this hybrid method, Chemcatcher® and commercial kit are used. This presentation will show comparison between concentration data by LC/MS/MS and those by ELISA technique in grab water samples, calibration tests for sampling rates of neonicotinoid insecticides and their occurrence in surface water in Japan.

WE047

Does the settling of the resin beads have an impact on DGT measurements?

M. Jiménez, A. Altier, Universitat de Lleida and AGROTECNIO / Dep Quimica; J. Cecilia, Universitat de Lleida and AGROTECNIO / Departament de Matemàtiques; c. rey-castro, Universitat de Lleida and AGROTECNIO / Dep Quimica; J. Galceran, Universitat de Lleida / Dep Quimica; J. Puy, Universitat de Lleida and AGROTECNIO / Dep Quimica

DGT (*Diffusion Gradients in Thin Films*) is one of the most popular passive samplers for the determination of inorganic and organic fluxes (availability). Recent publications have shown that in presence of partially labile complexes, most of the metal accumulation in the DGT device comes from dissociation of the complex in the resin disc [1]. The distribution of the resin beads (in the resin disc) might, then, play an important role in metal accumulation. For simplicity, it is usually assumed that there is a homogeneous distribution of the binding sites in the resin [2]. However, it is well known that, during the preparation of the resin, the binding beads settle to one side of the disc. The influence of this inhomogeneity on metal accumulation (in presence of ligands) is here assessed using numerical simulation of DGT devices with resin beads in only one half of the resin disc. Results indicate that, due to the settling, there is a deficit in mass accumulation which increases as K (stability constant of the metal complex) increases[3]. The maximum deficit takes place for complexes with lability degrees close to 0.25, while very labile or inert complexes remain unaffected. A maximum deficit of 13% can be found when $Kc_L < 10^2$, but this deficit can increase up to 30% when $Kc_L < 10^3$ or up to 36.7% when $Kc_L < 10^4$ (c_L being the ligand concentration). Additionally, DGT devices with a stack of two resin discs can be used to estimate kinetic dissociation constants of complexes[2;4]. The influence of the inhomogeneity on the recovered kinetic constant is also analysed. It has been found that the recovered kinetic dissociation constant, $k_{d,recovered}$, and the true value, k_d, are practically proportional: $k_d \approx k_{d,recovered}/f$ being f the fraction of volume of the resin disc occupied by resin beads. This relationship is quite independent of the value of K and k_d. Funding from the Spanish Ministry MINECO (projects CTM2012-39183, CTM2013-48967) and from FEDER is acknowledged.

Investigation of trace element quantification alteration by fouling development on DGT passive samplers

D. Devillers, R. Buzier, A. Charriau, M. Grybos, G. Guibaud, University of Limoges / Research Group on Water Soil and Environment GRESE

The Diffusive Gradient in Thin Film technique (DGT) has been mainly developed for passive sampling of trace elements and its use for water quality monitoring is currently considered. Among the potential biases induced by sampler deployment in water systems, fouling of the protective membrane has been identified as potentially interfering elements diffusion in the sampler. Although numerous *in situ* deployments have been performed in water systems such as rivers, influence of fouling development on element quantification has been nearly not studied. This work proposes an investigation on fouling development on sampler and its influence on element quantification. For this purpose, three contrasted systems are studied: a conventional river, a wastewater impacted river and a stagnant pond. In each system, three types of membrane (cellulose acetate, polycarbonate and polyethersulfone) are deployed several weeks for fooling deposition and development. Membranes are then brought back to laboratory, incorporated into DGT systems and deployed in controlled solution (pH 7 and 10^{-2} M ionic strength fixed with $NaNO_3$) containing metals (Cd, Cu, Ni, Cr(III), Cr(VI) or Pb), metalloid (As) or nutrient (PO_4^{3-}) in order to determine their effective diffusion coefficient in the sampler. In parallel, fouling of the membrane is characterized through elemental analysis and observation with scanning electron microscopy coupled with X-ray microanalysis. Diffusion coefficient derived for fouled samplers will be presented and sampling biases induced by fouling will be quantified. Furthermore, link between diffusion coefficient alteration and composition of the fouling will be discussed.

WE049

Bioavailability assessment of copper in sediments using chemical methods and bioassay and the effects of potential adsorbents in remediation

K. Vaananen, S. Hietaketo, T. Oksanen, University of Eastern Finland / Biology; S. Abel, University of Eastern Finland / Department of Biology; G. Waissi, J. Akkanen, University of Eastern Finland / Biology

Metal contamination in aquatic environments is a growing concern. Bioavailability is the main factor determining toxicity of metals and therefore the use of bioavailability analysis is encouraged. Using adsorbents to reduce bioavailability and transport has been introduced as a novel remediation method for sediments contaminated by metals. In this study, we assessed the use of passive samplers (DGT) and pore water extracts (Rhizon) in assessing the bioavailability of Cu in a natural fresh water sediment. We also compared the results to a bioassay and evaluated the remediation potential and possible adverse effects of two adsorbent materials: chitosan and a biochar. The natural uncontaminated sediment was spiked with $CuCl_2$ (0–460 mg/kg dw) and subsamples were spiked with 0; 0.5 and 5 % (dw) chitosan or biochar. Total Cu concentration and bioavailable concentrations (DGT and Rhizon) were analyzed and the effects of Cu and/or amendments to biota were evaluated with a biotest (*Lumbriculus variegatus*). The functionality of the adsorbents was analyzed using DGT and Cu body residue in L. variegatus. There was a strong correlation between DGT and sediment total Cu concentrations between DGT and Rhizon samples. The growth of *L. variegatus* was reduced in chitosan-spiked sediments, but no adverse effects of biochar were seen. The bioaccumulation or Cu into *L. variegatus* increased together with total sediment concentration. On the basis of chemical methods, 5% chitosan reduced the availability of copper by 75–87 %. For biochar, no remediation potential was seen. DGT and pore water sampling gave comparable results for the bioavailability of Cu and they seem to be usable methods. However, neither chitosan nor biochar reduced the uptake of copper in the test organisms. Most of the studies of adsorbent materials for metals are focused on the chemical analysis of remediation potential, but this study shows that biological responses needs to be taken into consideration as well. The main uptake route of Cu *to L. variegatus* is seen to be through ingestion of sediment particles, which could partly explain the results. Since the uptake route of metals varies between different metals and species, further studies are still needed.

WE050

Does bioavailability of Zn from hydroponic media correlate with the free metal concentration or with the flux of a labile fraction?

M. Sedo, E. Companys, Universitat de Lleida and AGROTECNIO / Dep Quimica; J. Galceran, Universitat de Lleida / Dep Quimica; J. Puy, Universitat de Lleida and AGROTECNIO / Dep Quimica; O. Serra, Universitat de Girona / Biologia; R. Vera, Universitat de Barcelona / Dep Quimica; E. Antico, C. Fontas, Universitat de Girona / Dep Quimica

Zinc is an essential element for plant nutrition. In solutions, zinc exists in different chemical forms such as free hydrated ion, inorganic and organic complexes. The bioavailability of elements in the soil solution depends on their chemical speciation. Lipophilicity, global charge and lability of the complexes are the main factors that determine metal uptake by organisms and therefore information about speciation is crucial. For that, it is necessary to develop analytical techniques able to measure not the total metal in solution, but the free fraction or the labile ones. Four techniques, AGNES (Absence of Gradients and Nernstian Equilibrium Stripping)[1], ASV (Anodic Stripping Voltammetry), DGT (Diffusive Gradients in Thin films)[2] and Polymer Inclusion Membranes (PIMs)[3], are combined for this purpose in this work. DGT and PIMs are passive samplers. We present, for the first time, a comprehensive study of the application of these techniques in Hoagland hydroponic medium. AGNES provides the free Zn concentration. DGT, ASV provide availability fluxes associated to different labile fractions. An innovative approach based on PIMs has also been applied after optimization of parameters[4]. Zinc accumulation in the roots and shoots of *Solanum tuberosum* (potato plant) grown in hydroponic media with added Zn, and with or without the addition of organic ligands (humic acid, EDTA) has been measured. Correlations between the amount of Zn accumulated in the plant parts and the free and labile fractions measured in the hydroponic media with the different techniques have been evaluated. Funding from the Spanish Ministry MINECO (projects CTM2012-39183 and CTM2013-48967) is acknowledged. References: (1) Chito, D. et.al. *Sci.Total Envir.* **2012,** *421-422*, 238. Identification of contamination hotspots along a large river by silicone-based passive sampling

B. Becker, German Federal Institute of Hydrology; C. Möhlenkamp, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology; P. Lepom, German Environment Agency / Laboratory for Water Analysis; A. Paschke, Helmholtz Centre for Environmental Research UFZ; E. Claus, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology; S. Schaefer, Federal Institute of Hydrology / Biochemistry Ecotoxicology

Silicone-based passive sampling allows the quantification of time-weighted averaged concentrations (C_{TWA}) of hydrophobic organic chemicals (HOCs) in water, even in the low pg L^{-1} range. In previous studies, the suitability of passive sampling for the monitoring of HOCs was tested in different rivers in Germany. Thereby, the sampling site in the river Saar showed higher contamination with polycyclic aromatic hydrocarbons (PAHs) compared to the sampling sites in the rivers Elbe, Saale, Rhine and Danube. The river Saar originates in France and passes the Saarland conurbation before it flows into the river Moselle in Germany. The Saarland conurbation around the city of Saarbrücken is known as a former highly industrialised region with mining, iron and steel industries. In this study, we applied passive samplers for the identification of contamination hotspots along the German part of the river Saar. Silicone rubber sheets were exposed five weeks *in situ* at twelve sampling sites in May/June 2015. Sampling sites were located in the river Saar and its major tributaries, in the effluent of a waste water treatment plant and in the river Moselle after the confluence of the river Saar. Analyte-specific sampling rates (R_s) were determinedby *in situ* dissipation of performance reference compounds (PRCs). In the laboratory, passive samplers were extracted with n-heptane in a Soxhlet apparatus for 24-30 hours and extracts were analysed for polychlorinated biphenyls, dichlortriphenyltrichlorethane and its metabolites as well as PAHs by GC-MS/MS. For the determination of C_{TWA} in water, R_s of target analytes were modelled by non-linear least square regression of the fraction of retained PRCs according to Rusina et al. [1]. Preliminary results show that C_{TWA} of HOCs were mostly in the pg L^{-1} range with single PAHs up to few ng L^{-1}. In general, C_{TWA} of HOCs were higher in the river Saar than in the river Moselle after confluence of both rivers**.** Passive sampling data will be compared to aqueous concentrations determined by conventional chemical analysis of composite samples. Furthermore, the chances and limitations of the application of silicone-based passive sampling for regulatory chemical monitoring in regard to the European Water Framework Directive will be discussed. WE052

An innovative receiving phase for passive sampling of polar and apolar pesticides in surface waters

A. Martin, Irstea / Laboratory for chemical analyses of aquatic environments; C. Margoum, A. Jolivet, M. Le-Dréau, Irstea Lyon / Laboratory for chemical analyses of aquatic environments; M. Coquery, Irstea Lyon-Villeurbanne / UR MALY; J. Randon, University Claude Bernard Lyon / Institute of Analytical Sciences UMR

Silicone rubber (SR) has been successfully implemented as a receiving phase in various passive samplers (MESCO, Passive SBSE and silicone rod/sheet). Indeed, SR is mechanically resistant, insoluble in common solvents used for compound desorption, and enable a thermal desorption at high temperature. Nevertheless, SR is an hydrophobic material which permit mainly enrichment of apolar organic compounds (log $K_{ow} > 3$) from water (organochlorine pesticides, PAHs, PCBs, etc.). To remedy this lack of measurement representativity, the use of an other passive sampler in co-deployement for polar organics, as Polar Organic Chemical Integrative Sampler (POCIS), is the stategy preferred. This work aimed at testing the affinity of an innovative material for more polar organic compounds using passive samplers with a single receiving phase. In this way, a **Polar/Apolar Composite Silicone Rubber (PACSiR)** was developed for sorption of a wide range of organics compounds. First, this innovative composite material was assessed in laboratory for pesticides sorption whith a large range of physico-chemical properties. Then, PACSiR was shaped and calibrated as a passive sampler in laboratory, to be finally applied for the monitoring of several pesticides in surface waters. Extraction recoveries determined experimentally for 22 pesticides were similar or higher for all pesticides than for SR. The enhancement of extraction performances is the highest for polar pesticides, with log K_{ow} below 3, which are poorly sorbed on SR. Kinetics of uptake of pesticides in calibration system were mainly described by a pseudo-linear equation model for 14 days exposure. Sampling rate and partition coeficient were determined for calculation of time weighted average concentration (TWAC). Sampling rates for PACSiR passive sampler were 1.3 to 12.5 higher than for SR depending on the pesticide. Consequently, PACSiR enable to reach lower LOQ than SR for polar pesticides. Finally, results of field exposition of passive samplers in rivers were compared with grab sampling to access the occurrence of pesticides and to estimate the TWACs during field exposition. This study demonstrated that the PACSiR is a sensitive receiving phase for pesticides which can greatly improved sorption properties comparared to SR and permitted to reach lower LOQ for polar pesticides. Further experimental investigations on accumulation of other organic compounds will be carried out (hormones, pharmaceuticals, PAHs and PCBs).

WE053

Passive sampling of anionic herbicides (bentazon, chlorsulfuron, ioxynil and mecoprop) by DGT technique

R. Guibal, A. Charriau, R. Buzier, S. Lissalde, G. Guibaud, University of Limoges / Research Group on Water Soil and Environment GRESE

POCIS (Polar Organic Chemical Integrative Sampler) is the most commonly used passive sampler for the study of polar pesticides (POCIS-HLB) and, recently, of ionic pesticides (POCIS-MAX). Some limitations, regarding the influence of environmental parameters (such as water flow rate) on sampling rates, are however recognized. The DGT (Diffusive Gradients in Thin films) device is less affected by this limitation since uptake from the exposure medium is controlled by diffusion through a diffusive layer. An abundant litterature documents the application of DGT to inorganic compounds such as trace metals or phosphorus and recent developments have been done for few organic compounds, *i.e.* bisphenols, antibiotics, 4-chlorophenol, glyphosate and aminomethyl phosphonic acid. This work aimed at investigating the applicability of a DGT device for the monitoring of herbicides (bentazon, chlorsulfuron, ioxynil and mecoprop) present in an anionic form at natural water pH. DGT diffusive and binding gels were prepared with crosslinked polyacrylamide and OASIS® MAX was used as the binding resin. Pesticide analysis was performed by High Performance Liquid Chromatography combined with Time of Flight Mass Spectrometry. After exposure and dismantling, the binding gel was eluted in a methanol – 1M formic acid mixture (90/10) and the eluted mass was used to calculate the time weighted average concentration (C_{DGT}). Water samples were also collected during the experiments to determine pesticide concentration in bulk solution ($C_{solution}$). Diffusion coefficients of $4.32.10^{-6}$, $3.53.10^{-6}$, $4.97.10^{-6}$ and $4.20.10^{-6}$ $cm^2\ s^{-1}$ were determined at 25°C for bentazon, chlorsulfuron, ioxynil and mecoprop, respectively. The mass of pesticide accumulated by DGT increased linearly with exposure duration up to 10 μg per disk. Bentazon, chlorsulfuron, ioxynil and mecoprop (with pKa values of 3.28, 3.4, 4.1 and 3.11, respectively) are affected by solution pH. For bentazon and mecoprop, the performance of DGT seems to be unaffected by pH in the range 4 to 8. For ioxynil, an increase of pH from 5.0 to 8.0 led to the decrease of C_{DGT} / $C_{solution}$ by appromately 17%. Ionic strength increase was found to slighly affect bentazon and chlorsulfuron sampling only. The tested binding phase was found to be suitable with long term deployments and robust over the pH range of natural waters. DGT appears therefore to be a promising tool for measuring time-weighted average concentrations of anionic pesticides in waters.

Persistent and mobile contaminants in the aquatic environment: how to identify, analyse and regulate a potential threat for drinking water resources (P)

WE055

Using REACH registration data for the identification of persistent, mobile and toxic (PMT) substances to protect raw water resources

M. Neumann, Federal Environment Agency (UBA) / Section IV Chemicals; L. Vierke, D. Sättler, Federal Environment Agency UBA / Section IV Chemicals

Chemical substances and their uses that fall within the scope of the REACH Regulation (EC No. 1907/2006) have to be registered at the European Chemicals Agency (ECHA) in Helsinki. Registrants are requested to ensure a high level of protection of human health and the environment. By doing so, industry guarantees the safe use of chemicals throughout the whole life cycle. Raw water resources used for the production of drinking water need a high level of protection. In Europe drinking water is obtained mainly from groundwater, reservoirs or river bank filtration. If these environmental compartments are exposed to hazardous chemicals a contamination of drinking water is possible. In the last decade the fate and behaviour of substances in the aquatic environment has been investigated both scientifically and from a regulatory perspective. The finding is that the intrinsic hazard potential of a substance with respect to raw water contamination is maximised if the substance is at the same time persistent in the environment and mobile in the water cycle. Once emitted, these substances remain in the aquatic environment and the contamination is irreparable. If in addition they also fulfil the properties of being toxic any emission into water resources should be avoided during the production and downstream use of these substances. Kalberlah et al. (2014) present a proposal for an assessment concept of persistent, mobile and toxic chemicals (PMT substances). We show that the assessment concept for PMT substances uses the same set of data provided as standard information requirements for the registrations under REACH. It may builds the basis for regulatory measures by authorities. From an authority point of view such a contamination may be of equivalent concern as those substances with persistent, bioaccumulative and toxic (PBT) properties. So far, a potential for raw water contamination by PMT substances is not part of the standardized assessment under REACH. Kalberlah et al. (2014) also published a proposal for a practical guide. Therefor our assessment concept may also be applied by registrants under REACH to fulfil their responsibilities under REACH and ensure a safe use of chemicals.

WE056

Interpretation of Residue Data from a Groundwater Monitoring Study to Define Environmental Safe Use

D. Wallace, Environmental Safety Environmental Fate; J. van de Veen, ARCADIS; A. Newcombe, ARCADIS US Inc; p. kott, RTI International; p. Sweeney, Syngenta / Community Health and Epidemiology; P. Hendley, Phasera Ltd

*Current regulations governing the registration of plant protection products in the European Union (1107/2009) mandate that an assessment for the potential to reach groundwater is made. A recent Sanco opinion (*Sanco/13144/2010 rev. 3) has *provided guidance on demonstrating "safe use" through monitoring; specifically, 90% of the analyses, obtained from at least 50 locations would need to be less than EU trigger values in order for the Commission to consider a proposal for EU level approval. In 2012, a groundwater monitoring study was initiated with the objective of deriving a statistically valid 90th and 95th percentile concentration for the non-relevant S-metolachlor metabolites CGA354743 (ESA) and CGA51202 (OXA). From 796 quarterly samples collected from 124 locations across 11 European countries over a time period of 12-24 months , for OXA, 40% (321 samples) were < LOQ and >99% (789 samples) were < 10 µg/L. Despite the seven isolated OXA detections >10 µg/L, no site was found to have a long term average >10 µg/L which provides statistically valid confirmation of safe use. For ESA, 16% (126 samples) were < LOQ and 97% were < 10 µg/L (774 samples). Of the samples >10 µg/L (22 samples; 2.7%), only 5 sites were found to have a long term average >10 µg/L with no sites demonstrating analytical residues consistently >10 µg/L. The 90th and 95th percentile of ESA concentration was derived using sampling survey statistics and these were determined to be significantly below the EU trigger. Even using a worst-case assessment of the maximum site average in each relevant FOCUS zone, Châteaudun, Piacenza and Thiva residues were 10 µg/L,this indicated that exceedances are not widespread. The relative vulnerability of the sites was determined by linking the actual field properties back to the original European cumulative distribution of ESA mass flux, placing 35% of the sites above the 90th centile of vulnerability. In conclusion, this exceptionally thorough monitoring study across 124 randomly selected locations supports the "safe use" of S-metolachlor on the basis that both the 90th and 95th confidence intervals for OXA and ESA were < 10 µg/L.*

WE057

Carbamazepine and degradation by products in watershed and effluents

a. togola, C. SOULIER, BRGM / Laboratory Division

Carbamazepine, as antiepileptic drug is well-known as anthropic pollutant in WWTP effluent as well as in surface and groundwaters. Together with this ubiquist compound, different studies highlight the occurrence of several degradation products. But origins of the degradation products (degradation in WWTP, in surface water or soil, etc…) are more or less elucidated, due to few works considering all the compartment in the same study. In this work we have considered an alluvial plain impacted by several WWTP, with well-known connections between ground and surface waters. Influent and effluent of main WWTP stations were analyzed monthly to well characterize the pollution sources. Two sampling campaigns have been undertaken for simultaneous pot sampling of groundwater, surface water and effluents. In each case, carbamazepine and its main metabolites (10,11 dihydro 10 hydroxycarbamazepine, 2-hydroxy-carbamazepine, 10,11 epoxide- carbamazepine) and oxcarbazepine were analyzed. In parallel, High Resolution Mass Spectrometric analysis was applied to screen for unexpected degradation by-products. High persistency of carbamazepine and its main degradation products can be highlighted during wastewater treatments, combined with low level of detection and concentration in the watershed. HRMS data give useful information concerning occurrence of unexpected compounds, that allow a better understanding of carbamazepine's fate and behavior.

WE058

Identification of pesticides and their transformation products in groundwater

C. SOULIER, a. togola, BRGM / Laboratory Division

Nowadays it is increasingly important for public policy to know what compounds are present in groundwater and which of them must be monitored. This implies the need of specific analytical methodology to identify these micropollutants, emerging substances or transformation products present at low concentrations. The high resolution mass spectrometry (HRMS) has gained increasingly in importance for monitoring these organic compounds. Its high resolving power, mass accuracy and the sensitive full spectrum acquisition are the key points. On the other hand, the main difficulties for the implementation of monitoring are sometimes low and fluctuating concentration levels and complex mixture of pollutants. Therefore there is a strong interest to combine passive sampling to HRMS. Passive samplers allow accumulating compounds during exposure that improve trace detection and integrating pollution fluctuations. The Polar Organic Chemical Integrative Sampler (POCIS) was employed to sampling polar and semi-polar compounds (pesticides, pharmaceuticals, phenolic compounds, triazoles….). Two drinking water supplies were investigated and sampled during several months. Passive sampling was deployed monthly and analyzed by LC-QTof. To process data, different approaches were investigated. The first one is based on research from compounds listed on our homemade database (around 450 with experimental data on our system as retention time, exact masses for molecular and fragment ions) and suspect database (from bibliography and online databases). This suspect list was supplemented by crop protection agents and their degradation products of interest for these sites. The second approach concerns the non-target screening that could give information on the presence of other degradation products or unknown compounds present in all samples. These approaches allow highlighting the use of passive samplers as storage tool because more compounds are identified with POCIS. The use of these two techniques (passive sampler and HRMS) identified some target and suspect compounds present in groundwater on several month.

WE059

Neonicotinoid Pesticides in Drinking Water from Agricultural Regions of the Great Lakes Basin, Ontario, Canada

C.D. Metcalfe, Trent University / Water Quality Centre; S. Kleywegt, Ontario Ministry of the Environment / Standards Development Branch; T. Sultana, Trent University / Water Quality Centre

Neonicotinoid insecticides (NNIs) are widely used in regions of the Great Lakes basin in Ontario, Canada where there is intensive agriculture. Because of the persistence and high mobility of NNIs, there is concern that these insecticides may contaminate surface waters and groundwater in agricultural regions, including sources of drinking water. The objective of the project was to evaluate the distribution of NNIs and their metabolites in raw (untreated) and finished (treated) drinking waters in selected agricultural regions of southern Ontario, Canada. Raw and finished drinking waters were monitored with Polar Organic Chemical Integrative Samplers (POCIS) and grab samples collected from six drinking water treatment plants that draw their water in agricultural areas. The data from POCIS deployments indicate that there was contamination of raw water at concentrations < 25 ng/L, with clothianidin, imidacloprid, thiacloprid and thiamethoxam being the compounds most widely detected. The frequency of detection of NNIs was much lower in finished drinking water, but some of these compounds were detected with POCIS samplers at estimated concentrations in the low ng/L range. The data from grab samples of raw and finished drinking water collected at the time of POCIS deployment and retrieval, respectively showed good agreement between measured concentrations and the concentrations estimated from POCIS, although concentrations of NNIs in grab samples collected from finished drinking water were all below detection limits. Even though NNIs have been shown to have low toxicity to vertebrates, including humans, contamination of drinking water by this class of insecticides is still a cause for concern.

WE060

Fate of Persistent Organic Pollutants: Surface Water and Sediment

A. Aleksandryan, Hazardous Substances & Waste Policy Division / Head of Division; A. Khachatryan, Waste Research Center

For monitoring studies the samples of surface water and sediment were taken and analyzed for the probable content of persistent organic pollutants (POPs), organochlorine pesticides (OCPs) and polychlorinated biphenyls (PCBs) of the Republic of Armenia. The study involved Sevan Lake, rivers Masrik, Martuni, Gavaraget, Hrazdan, as well as water reservoirs "Yerevanyan" and "Akhpara". Gas-Chromatograph/ Mass-Spectrometer GCMS-QP2010 SE EI 230V CELV incl. GC-2010 Plus(Shimadzu Corporation, Japan) was used for analyses. The following pesticides were revealed in studied samples: Hexachlorcyclohexane; DDT; Heptachlor; Hexachlorbenzene; Aldrin; Dieldrin; Endrin; Mirex. As revealed, in all tested samples of surface water the residual amounts of pesticides were revealed at microgram levels. DDT was determined only in Masrik and Gavaraget rivers; in other water basins only products of DDT degradation were found: DDE and DDD. A typical picture of PCBs-related anthropogenic pollution was also observed. The attention should be paid to the presence of great amounts of congeners; this also confirmed the fact of technogenic pollution, viz.: transformer oils were the source of pollution. The peculiarities of POPs transformation along the trophic chains of the hydroecosystem were revealed: the process of PCBs accumulation occurred from the lower to the higher trophic levels. The research performed for determination of POPs content in samples of water, hydrobionts and bottom sediment of theLakeSevanand major rivers ofArmeniaallowed to assess the degree of their bioaccumulation in the hydroecosystem. The high content of POPs in bottom sediment might pose danger for penetration of these substances to human organism – through hydrobionts, detritophages. The process of PCB accumulation most intensively proceeds in hydroecosystems. Being deposited in bottom sediment, through the detritophages, they are involved in the turnover of substances. The research results showed that PCBs content in the studied samples exceeded the hygienic standards. The level of PCBs is dictated by the presence and use of PCB-containing oils in the power-production complex (capacitor, transformer oils, etc.) Monitoring studies revealed presence of PCBs in all tested samples of water from reservoirs of the Republic of Armenia; PCBs content in bottom sediment exceeded the level of these substances in water basins of the country by 1-2 orders of value.

WE061

Biliary PAHs metabolites in red mullet (Mullus barbatus) from Spanish Mediterranean coast

. Gea-Pacheco, R. Moreno-GonzÃlez, Instituto EspaCol de Oceanografia / Centro Oceanogryfico de Murcia; C. Martinez-Gomez, Instituto EspaCol de Oceanografia / Marine Contamination and Biological Effects; J.A. Campillo, V. Leyn, Instituto EspaƷol de Oceanografia / Centro Oceanogryfico de Murcia

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous organic contaminants present in marine environment as a consequence of their continuous input from either land- or marine-based sources. Fishes have a higher capacity to uptake, metabolize and excrete PAHs than invertebrates such as molluscs, therefore the accumulation of PAHs metabolite in their bile fluid can be used to assess the environmental exposure to the parent compounds. In this study the bile concentration of PAHs metabolites in red mullet (*Mullus barbatus*) from 10 areas from the Spanish Mediterranean coast were characterized (Barcelona, Ebro Delta, Tarragona, Mallorca, Valencia, Santa Pola, Cartagena, AlmerCa, Castell de Ferro and Mlaga). Red mullets from 12 to 18 cm were sampled in autumn 2012, 2013 and 2014. Bile samples were treated individually and maintained at -20BC until analysis. In addition the PAHs profile was analyzed in samples of muscle of the same specimens in order to compare the relationships between the PAH bioaccumulation and the PAH bile levels. Phenanthrol and pyrenol were the major PAH metabolites detected in the red mullet bile, and their concentrations were analyzed by liquid chromatography with fluorescence detection using a standard solution for external calibration. Phenanthrol and pyrenol were found in all samples, with pyrenol reaching the highest concentrations. The metabolite concentrations were higher in specimens sampled close to Barcelona than in the rest areas. In contrast, the minimum values were found in Castell de Ferro. These results showed that accumulation of PAHs metabolites was related with the human pressure. Thus phenanthol and pyrenol concentrations in red mullet bile represented better their PAHs exposition in the marine environment than PAHs concentrations in muscle due to the high hepatic metabolism in red mullet.

Effects of Clay Minerals on Diethyl Phthalate Degradation

J. Gao, Institute of Soil Science, CAS / Key Laboratory of Soil Environment and Pollution Remediation CAS

Phthalate esters are a group of plasticizers used to increase plastic flexibility, transparency, durability, and longevity. They have been detected in China's agricultural and industrial soils. In this study, effects of clay minerals on diethyl phthalate ester (DEP)'s Fenton reaction were examined. The results showed the absorption of DEP to different clay minerals could significantly reduce DEP degradation. The clay minerals with low Fe content would quench free radicals and reduce DEP degradation in solution, and adsorbed DEP would not be degraded. However, the clay minerals with high Fe content would produce more free radical and accelerate DEP degradation in solution, and adsorbed DEP could be degraded. This study implied that clay types, compound structure, exchangeable cation played important roles in phthalate ester's degradation.

WE063

Per- and polyfluoroalkyl (PFASs) contamination profiles in water and sediments for two contrasting lakes in southern and northern Sweden

D. Mussabek, Lunds Tekniska Högskola, Lunds universitet / Water Resources Engineering; R. Berndtsson, K.M. Persson, Lund University / Department of Water Resources Engineering; L. Ahrens, Swedish University of Agricultural Sciences (SLU) / Dept of Aquatic Sciences and Assessment; K. Jakobsson, University of Gothenburg / Department of Public Health and Community Medicine

Perfluoroalkyl and polyfluoroalkyl substances (PFASs) are becoming an increasingly global concern. PFASs are highly fluorinated organic chemicals that represent a serious risk for environmental and human health. Due to their toxicological impact, PFASs are now included in several emission regulations. Even if the global level of PFASs use is decreasing much of present concentrations in the environment are results of usage and exposure in the past. Therefore, observation of current environmental concentrations and transport patterns may lead to better prediction of their potential environmental distribution, health impact, and future fate. Investigation of PFASs distribution profiles was carried out in surface waters and sediments of the two lakes Sänksjön and Langsjön in southeast and northeast of Sweden. In total 11 sediment cores and 6 water samples were collected to investigate the PFASs concentration by using high-performance liquid chromatograph-tandem mass spectrometer (HPLC-MS/MS). The concentration of PFASs in sediment ranged from 2.7 to 216 ng g^{-1} dry weight for the Sänksjön lake and from 0.8 to 78 ng g^{-1} dry weight for the Langsjön lake. The PFAS concentrations and distribution were correlated to investigate transport conditions for different PFASs and to determine the possible exposure time sequence for each sampling site. Selected water and sediment properties such as pH, conductivity, and total organic carbon were correlated to observed PFAS concentrations. The results for water samples reflect the high contamination of surface water in both lakes. The maximum concentrations were 79 and 1885 ng L^{-1} for Sänksjön and Langsjön, respectively. Analysis of sediment cores reflects the temporal evolution of discharge patterns to the two lakes. The correlation of selected samples suggests transport and degradation mechanisms.

WE064

Evaluation of a suspected-target and non-target high-resolution mass spectrometry method for the preliminary detection of contaminants of emerging concern in water samples impacted by wastewater

A. Huba, Florida International University / Chemistry Biochemistry; P.R. Gardinali, Florida International University / Chemistry Biochemistry and SERC

In our continuously growing society, there is a constant production, use, and disposal of products such as antibiotics, flame retardants, personal care products, pharmaceuticals, and pesticides/herbicides. Such products eventually enter the water cycle, where they can persist and negatively affect ecosystems, which represents one of the primary current areas of environmental concern. Further, all of these compounds, which fall under the broad term of contaminants of emerging concern (CECs), can undergo multiple transformation processes, such as photolysis, oxidation, or microbial degradation, and thus be modified into new, and sometimes equally as concerning, compounds. Recent focus has shifted from a targeted analysis, which limits the monitoring to a small set of predefined compounds, to a suspected-target or non-target analysis. This workflow allows for a much more comprehensive screening of analytes, requires no "a priori" knowledge on what compounds are of interest, and allows for the monitoring of transformation products (TPs). The ability of doing such non-targeted analyses, can be mainly attributed to developments in high-resolution mass spectrometry (HRMS), allowing the assignment of molecular formulae, which in combination with other confirming tools (e.g., retention time, isotopic pattern, MS/MS fragmentation data) can be used to identify specific compounds. The current study uses an Orbitrap Q Exactive mass spectrometer, which provides excellent sensitivity and selectivity in full scan, in order to perform suspected-target and non-target screening of CECs and their TPs. The analysis includes

HESI-UPLC-MS full scan analysis at a resolution of 140,000, as well as MS/MS fragmentation data, and the use of the Compound Discoverer software for compound identifications. Two types of sampling methods will be evaluated in combination with this analytical workflow. Firstly, grab samples will be filtered and subjected to a liquid-liquid extraction performed at two pHs (4 and 10) in order to maximize the compound range. Secondly, complementary samples obtained from a polar organic integrative sampler (POCIS) will also be analyzed. This will help to critically assess the capability of this sampling method to obtain polar organic chemicals that may be lost in traditional liquid-liquid extractions.

WE065

Stationary phase selection in HILIC: a study about stationary phase retention properties and the influence of mobile phase parameters

D. Zahn; T. Frömel, T.P. Knepper, Hochschule Fresenius, University of Applied Sciences

Persistent and mobile organic micropollutants may pose a threat to drinking and raw waters, and thus need to be monitored and regulated. A high polarity increases the chance of chemicals to be mobile in the water cycle significantly since it leads to good water solubility as well as low volatility and adsorption and thus enables those chemicals to pass most natural and artificial barriers unhindered. The same properties that make organic substances of high polarity potentially relevant for drinking and raw waters also exacerbate their analysis. GC-MS and RP-HPLC-MS, the two predominantly deployed methods in organic trace analysis suffer from insufficient volatility or retention while many alternatives like the use of ion pair reagents, capillary electrophoresis, NP-HPLC and ion chromatography have major drawbacks in combination with mass spectrometry or are limited to ionic compounds. While hydrophilic interaction liquid chromatography (HILIC) has proven to be a versatile tool for the analysis of highly polar organic compounds and is well compatible with mass spectrometry, the technique is not yet widely established. This may be a consequence of the complexity of the multimodal retention mechanism, the availability of a variety of dedicated HILIC stationary phases, the importance of stationary phase selection and the lack of an almost universally applicable stationary phase chemistry such as C18 in RP-HPLC. As a consequence, stationary phase selection is one of the most crucial steps in HILIC method development and in-depth knowledge is required for a suitable selection. Several studies investigated the retention properties of HILIC stationary phases, but most were limited to either analytes of a specific substance class or stationary phases with similar functionality. More broad attempts encompassing a wide range of stationary phases and analyte classes are still rare. In this study we investigated the retention behaviour of 19 model analytes on twelve HILIC stationary phases with different mobile phase compositions. The results allowed a grouping of stationary phases based on their retention properties and selectivity which facilitates stationary phase selection for method development and optimization. A comparison of the retention properties at different mobile phase compositions provides valuable information about the intrinsic optimization potential of important mobile phase parameters, possibly facilitating future HILIC method development.

WE066

Environmental and Metabolic Transformations of the Piscicide, Antimycin A

J. Kenneke; T.J. Sack, Senior Service America Incorporated

Antimycin A is an extremely potent inhibitor of mitochondrial respiration and has been used extensively as a piscicide to eradicate non-native fish species and in aquaculture (e.g., catfish) for the selective removal of scaled fish from ponds prior to restocking. In spite of the long-term use of antimycin A, little information exists on its environmental fate and metabolism. Antimycin A is a bacteria fermentation product containing a nine member dilactone ring and exists as a mixture of eight structural isomers that differ in their dilactone alkyl chain (hexyl or butyl) and acyloxy side chain (butyl or propyl). A high performance liquid chromatographic analytical method was developed for the measurement of antimycin A isomers: $4_{a,b}$, $3_{a,b}$, $2_{a,b}$, and $1_{a,b}$ in aqueous and microsomal samples. Laboratory hydrolysis studies were conducted using certified buffers at eleven different pHs between pH 1 and pH 9. Both static and mixed batch reactors were used, and for the first time first-order abiotic hydrolysis half-lives were measured for individual antimycin isomers in addition to total antimycin. In vitro metabolism studies were conducted using rat hepatic microsomes at pH 7.4. Abiotic hydrolysis of the antimycin lactone occurred more quickly than hydrolysis of the acyloxy moiety. The rate of antimycin A hydrolysis increased with increasing pH. Antimycin $3_{a,b}$ hydrolyzed significantly slower than $1_{a,b}$, above pH 6 while $1_{a,b}$ hydrolyzed more slowly than $3_{a,b}$ below pH 6. At pH 8 and below, the mixed batch systems exhibited faster rates of antimycin A hydrolysis than the static system; above pH 8 the rates were nearly identical for the two systems. In vitro phase 1 metabolism led to the preferential hydrolysis of the antimycin A acyloxy group and deformylation of the N-formylaniline moiety. The four hexyl-containing isomers (1_a, 1_b, 2_a, 2_b) yielded the same metabolite; the four butyl-containing antimycin isomers (3_a, 3_b, 4_a, 4_b) yielded a second unique metabolite. Based on reports that binding of the antimycin A formylamino group is critical for inhibition of mitochondrial respiration (i.e., antimycin efficacy), we hypothesize that the metabolically-mediated deformylation of antimycin A could be a significant pathway for deactivating antimycin A—especially in the case of mammalian exposure (i.e., consumption of antimycin tainted fish). Additional work is ongoing to test this hypothesis.

Degradation Mechanism of Algal Derived Odorants by Chlorination and UV/Chlorination Processes

T. Kim, Seoul National University, Graduate School of Public Health / Department of Environmental Health Sciences; M. Kim, Environmental Health / Department of Environmental Health Sciences; K. Zoh, Seoul National University / Department of Environmental Health

Microbial activities can degrade the quality of drinking water sources by the release of algae derived organic matters including algal toxins and undesirable taste and odor (T&O) causing compounds such as 2-methylisoborneol (2MIB) and geosmin. These T&O compounds have a possibility to be the precursors of trihalomethanes (THMs) as well as other hazardous by-products during chlorination and other treatment processes due to their strong oxidation potentials. Furthermore, the conventional water treatment processes (coagulation, sedimentation, and filtration) are not effective for removing these T&O compounds. For effective treatment of 2MIB and geosmin, the investigation including the identification of their by-products formed during applies processare needed. In this study, chlorination, UV photolysis, and UV/Cl_2 reactions were applied to treat (2MIB and geosmin in water. While chlorination was ineffective to the removal of GSM and 2MIB, UV photolysis and UV/chlorination reactions effectively removed both compounds. This may due to the destruction of tertiary alcohol structure which has a resistant to chlorination. UV photolysis and UV/chlorination reactions followed the pseudo first-order reaction. Neutral pH was effective for the removal of geosmin and 2MIB, due to that OH radical scavenging by OCl^- ion at higher pH. The intermediates identified by GC/MS scan mode (m.w. range 50 to 300) during UV/Cl_2 reaction were 1,4-dimethyl-admantane, 1,3-dimethyl-admantane, and *cis*-1-ethylideneoctahydro-7a-methyl-1H-Indene for geosim, 2-methylenebornane, and 2-methyl-2-bornene for 2MIB). Also, 4-methyl-2-heptanone, 2,4-dimethyl-1-heptene, and 2-methyl-3-pentanol were detected from both 2MIB and geosmin. These intermediates were produced by the rearrangement, bond scission, and ring opening. These intermediates decreased with further reactions, and the formation of chloroform with further reaction. Using the obtained information, the degradation pathways of UV/chlorination of 2MIB and geosmin were constructed.

WE068

Chemical and microbial markers to identify human-associated contamination in Kokemäenjoki watershed

N. Perkola, Finnish Environment Institute, SYKE; T. Pitkänen, A. Kauppinen, National Institute for Health and Welfare / Water and Health Unit

Microbial and chemical contaminants can be used as source tracking markers in the environment. Accurate identification of pollutant sources in watersheds is crucial for ensuring a good water quality. Ideal human markers are specific i.e. their source is solely anthropogenic. They should also be detectable even at long distances from the source. Sources and distribution of chemical and microbial human markers in Kokemäenjoki watershed, Finland, were studied as a part of Aquatic contaminants - pathways, health risks and management (CONPAT) project. Municipal and industrial wastewaters, surface waters, and artificial ground water were sampled 8-9 times during two years. The feasibility and ability of different markers (i.e. acesulfame, human adenoviruses and human-specific fecal bacteria markers) to indicate human fecal pollution was evaluated. Chemical source markers are typically water soluble compounds that are continuously released to environment at easily detectable concentrations. Artificial sweetener acesulfame is an ideal human marker, since it is commonly used, does not decompose in wastewater treatment, and is persistent in the aquatic environment. It was detected in all studied samples. Fecal indicator bacteria are commonly used for the evaluation of water quality in relation to the potential human health risks. However, the origin of fecal pollution can be either humans or animals and bacterial indicators might decay in the environment with different rate than pathogens such as viruses. Human infecting adenoviruses and human-specific *Bacteroidetes* species are commonly found in sewage and from human-impacted watersheds. We used DNA-based qPCR to characterize human-derived pollution. However, the DNA of the dead microbes may persist in the environment. Metabolically active cells usually contain higher numbers of ribosomes than dormant cells. Therefore we developed RNA-based techniques to characterize active microbial populations. Adenoviruses were common in the CONPAT study area; 62% of the surface water samples contained low numbers of adenovirus gene copies. Human-specific source identifier HF183 was present in all surface water samples. However, the HF183 copy numbers varied greatly depending on the environmental factors such as the diluting effects and distance from the municipal sewage discharge points. Furthermore, the rRNA:rDNA ratio indicating the activity level of the HF183 bacteria group was highest in the most polluted locations.

WE069

Development of a compact continuous submerged water samplers for

monitoring micropollutant time-weighted average concentrations using a 3D printer

Y. Kameda, Chiba Institute of Technology / Civil Architectural and Environmental Engineering

Grab sampling is a very basic and effective sampling method to measure micropollutants in surface water when the "sampling frequency" is high. However, high frequency is difficult in most investigations and screenings. Passive sampling techniques have great advantages to estimation of time-weighted average concentration and accumulation monitoring during their deployment. But passive sampling techniques have also disadvantages to measuring micropollutants in dissolved form and laborious calibration of sampling rates for micropollutants. Recently small continuous low-level aquatic monitoring "C.L.A.M." has been developed which can perform low flow rate extraction sampling at sampling sites. C.L.A.M. is very effective tool to estimate micropollutant concentration in low turbidity surface water. Therefore it is very meaningful to develop novel samplers to monitor micropollutants in particulate and dissolved form even in muddy surface water during several weeks. In this study, a novel sampler which can concentrate dissolved micropollutants at constant flow rates in surface water even with high concentration of suspended solids. Disks which absorb micropollutants in surface water are Empore disks. A filter upon the disk is a 47mm hydrophilic PTFE membrane filter. A flow cell which houses an Empore disk and PTFE membrane is developed using a 3D printer. This presentation will show various developed flow cell models and their filtration characteristics which is very important to build a novel sampler.

WE070

Polycyclic aromatic hydrocarbons in water of Bangladesh

M. Shoeb, University of Dhaka / Deaprtment of Chemistry; A. Sultana, M. Nazimuddin, S. Sarker, M. Mamun, N. Nahar, University of Dhaka / Department of Chemistry

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous in nature and widely found in plant, air, soil and water. Anthropogenic activities e.g. motor vehicles, industrial processes, domestic heating, waste incineration etc. are major sources of PAHs to the environment. Due to their carcinogenicity, the water pollution caused by PAHs is a great concern worldwide. Dhaka, the capital of Bangladesh with an inhabitant of 20 million people is vulnerable for the anthropogenic activities. In order to evaluate the level of PAHs, 30 water samples were collected from three big rivers namely Megna, Buriganga and Turag that surround the city and Lake Gulshan within the city. The target polycyclic aromatic hydrocarbons (PAHs) were anthracene, fluoranthene and benzo[a]pyrene. Solid phase extraction using C-18 cartridge was used for the pre-concentration, extraction and clean up, and finally acetonitrile was used for elution of PAHs. High performance liquid chromatography coupled with fluorescence detector (HPLC-FLD; excitation wavelength: 340 nm, emission wavelength: 425 nm) using water-acetonitrile (5:95) isocratic solvent system was used for the identification and quantification of PAHs. The limit of detection (LOD) was 200, 0.63 & 0.63 ng/L and limit of quantification (LOQ) was 660, 2.1 & and 2.1 ng/L for anthracene, fluoranthene and benzo[a]pyrene, respectively. The calibration curves were linear and the correlation coefficients (r^2) were 0.994, 0.997 and 0.998 for anthracene, fluoranthene and benzo[a]pyrene. Good recoveries were obtained for the target analytes (anthracene, fluoranthene and benzo[a]pyrene) and ranged from 91, 85 and 96%, respectively. Analysis of PAHs by HPLC-FLD method has successfully been established after validation. Out of 46 samples, fluoranthene was found in 32 samples in the range of 1.89-1190 ng/L and anthracene was found in 2 samples (1800 and 2900 ng/L). Benzo[a]pyrene was not found in any sample.

WE071

Determination of several organophosphorus triesters in mollusks by pressurized liquid extraction and liquid chromatography-mass spectrometry

R. Montes, University of Santiago de Compostela / IIAA Institute for Food Analysis and Research; M. Rial, J. Quintana, R. Cela, R. Rodil, University of Santiago de Compostela

Phosphoric acid triesters are mainly employed as plastic additives, as flame retardants and as plasticizers, but are also used in many other applications, such as in hydraulic fluids, paints and several industrial processes. Many of them are considered as high production volume chemicals and moreover, phosphoric acid triesters usage is growing due to the ban on the use of most polybrominated diphenyl ethers (PBDEs) as flame retardants. When used as plastic additives, phosphoric acid triesters are not chemically bonded but simply mixed with the bulk material they are intended to protect, and so they are relatively easy to release into the surrounding environment. Thus, they have been detected in a range of environmental compartments, like air, water and sediment, and more recently marine biota, which could contribute a health safety issue. Information on these compounds analysis it however limited to very few samples and the most popular triesters only. The aim of this work was the development of a comprehensive method for the extraction and determination of several classes of organophosphorus triesters (including alkylated, arylated and chloro- and bromo-alkylated) in mollusks samples. Pressurized solvent extraction (PLE) integrating a clean-up process was employed as sample preparation technique and liquid chromatography coupled to mass (LC-MS) for separation and determination. The extraction conditions (solvent, sorbents, temperature, time and number of cycles) were optimized maximizing both extraction and clean-up efficiencies. Blank problems associated with the presence of some of the analytes on the filters and on the sorbents were encountered and reduced by using thorough clean-up protocols. Validation of the method was evaluated by the study of linearity, accuracy, precision in terms of relative standard deviation (RSD) and limits of detection and quantification. Finally, the method was applied to different mollusks samples. *Acknowledgement* - This work is financed by MINECO, in the frame of the collaborative project EMERCONFO (CTM2014-56628-C3-2-R). We also acknowledge the support of *Xunta de Galicia* ("Consolidación" funds) and FEDER. We also thank the INTECMAR (Technological Institute for Monitoring of the Marine Environment in Galicia) for providing several mollusk samples

WE072

SimpleBox 4.0: improving the model while keeping it simple...

A. Hollander, RIVM / DMG; D. van de Meent, Radboud University / Department of Environmental Science

Chemical behavior in the environment is often modeled with multimedia fate models. SimpleBox is one often-used multimedia fate model, firstly developed in 1986. Since then, two updated versions were published. Based on recent scientific developments and experience with SimpleBox 3.0, a new version of SimpleBox was developed and is made public: SimpleBox 4.0. In this new model, eight major changes were implemented: removal of the local scale and vegetation compartments, addition of lake compartments and deep ocean compartments (including the thermohaline circulation), implementation of intermittent rain instead of drizzle and of depth dependent soil concentrations, adjustment of the partitioning behavior for organic acids and bases as well as of the value for enthalpy of vaporization. The effects of the model changes in SimpleBox 4.0 on the predicted steady-state concentrations of chemical substances were explored for different substance groups (neutral organic substances, acids, bases, metals) in a standard emission scenario. In general, the largest differences between the predicted concentrations in the new and the old model are caused by the implementation of layered ocean compartments.Undesirable high model complexity caused by vegetation compartments and a local scale were removed to enlarge the simplicity and user friendliness of the model.

WE073

Sediment fingerprinting in the catchment of the Dobczyce Reservoir (South Poland)

G.M. Zemelka,

Excessive fine sediment loadings delivered to a drinking water reservoir from a variety of sources in the human modified catchment have potentially detrimental impacts on aquatic environment and quality of drinking water. Therefore, we attempted to expand the existing state-of-art of the Dobczyce Reservoir (South Poland) research by including sediment fingerprint approach. The Dobczyce Reservoir is situated near Krakow (around 1,000,000 inhabitants) and supplies over 50% of drinking water to the urbanization. It is located in the agricultural and urban catchment. Due to the use of the reservoir as a drinking water source there are several limitations concerning the discharge of wastewater from the catchment. However, the existing studies indicate the presence of pollutants, particularly heavy metals. From the water quality management point of view it is important to determine the sources of pollution and sediments. Among the numerous approaches, the *sediment fingerprinting* has been recently recognized as a valuable tool. The main assumption of this approach is comparison of properties of suspended matter with samples coming from the catchment. In the case of studied reservoir the list of applied sediment fingerprints included a variety of chemical tracers among heavy metals and organic compounds. This *sediment fingerprints* uses chemical tracers, which include, among others: granulometry, radioisotopes, rare earth elements, heavy metals and organic compounds. However, they are expensive, time-consuming and require access to a specialized laboratory. Therefore, in the case of present research it was decided to stress mainly physico-chemical indicators (grain size distribution) and chemical indicators (N and P), heavy metals (Cr, Pb, Cu, Cd, Zn), and selected organic pollutants (PAH and nitro PAH) indicating the origin of the catchments anthropogenic. Research included sampling from the suspension and sediment in three seasons and two repeats (spring, summer, autumn). Sampling took into account the amount of precipitation and flow. This study extended the knowledge of geochemical pollution of the aquatic environment in the Dobczyce Reservoir and showed the source of suspension contamination *sediment fingerprints*.

WE074

Spatial distribution of legacy and emerging contaminants in sediments from the Western Adriatic Sea (Italy)

T. Combi, University of Bologna / Environmental Sciences; L. Langone, S. Miserocchi, National Research Council of Italy CNR / Institute of Marine Sciences National Research Council ISMARCNR; P. Lara-Martin, Universidad de Cádiz Spain / Physical Chemistry; M. Pintado-Herrera, Universidad de Cádiz Spain / Department of PhysicalChemistry; R. Guerra, University of Bologna / Environmental Sciences

FP7 PERSEUS project (Policy-oriented marine Environmental research in the

Southern European Seas) aims to identify the interacting patterns of natural and human-derived pressures on the Mediterranean and Black Seas, linking them to the Marine Strategy Framework Directive (MSFD) descriptors and indicators. Since marine sediments can affect the resident biota, aquatic-dependent wildlife, and human health, the analysis of contaminants in sediments is a key factor for comprehending the overall ecosystem quality. Moreover, the presence of numerous groups of contaminants in sediments are still poorly studied and represent a complex issue in terms of understanding the interaction mechanisms between different chemical compounds and possible environmental consequences. In this context, a monitoring survey (ADREX 14 Cruise) has been conducted in order to investigate spatial patterns of contaminants in sediments from the Adriatic Sea, Italy. Three groups of regulated compounds were analysed: PCBs, DDT (p,p'DDD, p,p'DDE and p,p'DDT) and PAHs. Total PCBs, DDTs and PAHs varied between 0.05 and 4.2 ng g^{-1}, 0.05 and 4.3 ng g^{-1} and 38.8 and 570 ng g^{-1}, respectively. Spatial trens revealed a common pattern, with decreasing concentrations from the northern to the southern Adriatic Sea, suggesting influence from the Po River, which is the major Italian watercourse. Diverse groups of CEC were analysed, such as personal care products (PCPs), which includes fragrances, UV-filters and antimicrobials, organophosphorus compounds and endocrine disruptors compounds. Concentrations of PCPs ranged from-1. Nonylphenol isomers ranged from-1 and organophosphorus ranged from-1. Although CEC also presented higher concentration in the Northern Adriatic, the spatial distribution was not as clear as the one detected for the regulated compounds. Fragrances and UV filters presented some increased concentrations close to turistic areas as the Gargano Promontory, Ancona and Bari, besides the Po River Prodelta area. This work provides an extensive data set on the contamination status of several groups of contaminants in sediments from western Adriatic Sea. Spatial trends suggested the Po River outflow to be a major contributor of pollutants to sediments in the Adriatic Sea. However, the patterns of some PCPs indicate point sources of these compounds, particularly in areas with higher human presence.

WE075

Polycyclic Aromatic Hydrocarbons in the Danube River Sediments: Potential source contributions and carcinogenic risk assessment

M. Brboric, University of Novi Sad Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; B. Vrana, Masaryk University, Faculty of Science, RECETOX / Environmental chemistry and modelling; S. Pap, University of Novi Sad Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; M. Vojinovic MIloradov, Faculty of Technical Sciences University of Novi Sad / Department of Environmental Engineering and Occupational Safety and Health; I. Mihajlovic, Faculty of Technical Sciences University of Novi Sad; J. Radonic, Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; M. Turk-Sekulic, University of Novi Sad / Department of Environmental Engineering and Occupational Safety and Health

The present investigation was undertaken to investigate potential pollution emission sources and carcinogenic risk of 16 priority PAHs in bottom sediments from the Danube River, Serbia. Three models (Diagnostic Ratios, Cluster Analysis and Principal Component Analysis–Multiple Linear Regression (PCA–MLR)) were applied to analyze the results obtained from ten collected bottom sediment samples. The total concentration of 16 PAHs ranged from 99.48 to 520.48 ng/g dw, with a mean (median) concentration of 271.86 ng/g dw (235.37 ng/g dw). Individual PAH analysis showed that four to six rings PAHs were the most frequently detected isomers and accounted 85% of the total PAHs concentrations. Source apportionment results derived from three different models, considering the whole dataset, were similar, indicating that the highest contribution to ∑PAHs was from: (i) coal combustion, (ii) vehicular emission and (iii) grass and wood combustion. PCA suggested that these three principal components could be the primary PAHs contributors, accounting for 73.7%, 16.0% and 5.5% of PAH concentrations, respectively. Diagnostic ratios showed that PAHs in the sediments of the Danube River were predominantly of pyrolytic origin, followed by petroleum origin (only two sites: ∑LMW/∑HMW=1.57 and 4.66, respectively). According to hierarchical cluster analysis, collected sediments cluster in three major groups, Low (4 localities), Moderate (4 localities) and High (2 localities) contamination that is a consequence of the proximity of the main industries complexes consisting of a petrochemical factory, oil refinery and a chemical fertilizer factory. PAH levels in sediments were compared with Sediments Quality Guidelines (ERL/TEL and ERM/PEL), which suggested that sediment of the Danube River did not show any ecotoxicologial risk for benthic organisms. The values of carcinogenic PAHs were in the range of 26.54 to 277.54 of ∑PAHs. The toxic equivalent concentrations of carcinogenic PAHs were 6.49-74.94 ng/g-BaPeq in Danube sediment, suggesting low carcinogenic risk for this area. **Acknowledgement:** Ministry of Education, Science and Technological Development, Republic of Serbia (III46009) supported this research.

Identification of pollution hotspots in Norwegian marine sediments using long-term data

G. Everaert, Ghent University / Laboratory of Environmental Toxicology and Aquatic Ecology; A. Poste, Norwegian Institute for Water Research; D. Hjermann, Norwegian Institute for Water Research NIVA; K. Borga, Department of Biosciences, University of Oslo / Department of Biosciences; L. Nizzetto, N.W. Green, NIVA Norwegian Institute for Water Research; A. Ruus, NIVA / NIVA

In the present research, we characterized spatiotemporal trends of sediment concentrations of chemical compounds in Norwegian marine waters. To do so, we made use of historical data available through the Norwegian state pollution monitoring programme and the coordinated environmental monitoring programme (CEMP). We used generalized additive models (GAMs) to infer the spatiotemporal trends of the concentrations of PCBs, PAHs and trace metals measured between 1986 and 2008 at 153 sampling locations. GAMs with time, organic carbon content, latitude and longitude as covariates explained ca. 80% of the variability in the log transformed sediment concentrations. For each of the compounds we identified historical pollution hotspots (e.g. Sørfjord (Western Norway) for mercury and zinc and Grenlandfjord (South-Eastern Norway) for PAHs). To identify the local and regional drivers of the contaminant concentrations at these locations we pair the contaminant data with other relevant environmental data (e.g. water chemistry, input data, climatic data and remediation measures). The present research demonstrates that long-term data can provide useful insights in the fate and distribution of chemicals in the environment. The extensive monitoring campaign results in a long series of data, however for some chemicals the design does not allow coherent temporal trend analyses.

WE077

Spatial patterns of target metals (Cu, Pb, Zn) in recent sediments from the Adriatic Sea

T. Combi, R. Guerra, M.L. da Rocha, University of Bologna / Environmental Sciences; L. Langone, S. Miserocchi, National Research Council of Italy CNR / Institute of Marine Sciences National Research Council ISMARCNR

The Adriatic Sea has been facing numerous environmental and climatic challenges due to increasing anthropic pressures, contributing to the input of nutrients and contaminants to this marine system. The final sink for most contaminants is the marine sediment, which can represent the final sink of a complex cocktail of priority substances. Hence, approaches combining multiple contaminants (e.g. metals and polychlorinated biphenyls - PCBs) are extremely important and can contribute to the overall environmental quality status of marine ecosystems. This work was developed under the PERSEUS EU Project (Policy-oriented marine Environmental research in the Southern European Seas), guided by the Marine Strategy Framework Directive (MSFD), which aims to achieve a Good Environmental Status until 2020 in European water bodies. Our aim was to evaluate spatial trends of trace metals (Cu, Pb and Zn) associated to the levels of PCBs in surface sediments of the Adriatic Sea. In order to assess contaminant levels and distribution, a monitoring survey was conducted from northern to the southern Adriatic in October 2014 (ADREX 14). Surface sediments were analyzed for sediment characteristics (e.g. grain size and organic carbon) and target trace metals. Generally, sediment samples collected around the Po River Prodelta (northern Adriatic) presented higher concentrations of metals and PCBs in comparison to the concentrations detected in central and southern Adriatic. This preferential accumulation in the northern Adriatic has already been documented in previous works on the Adriatic Sea and is mainly related to the influence of the Po River discharge, which is the largest Italian drainage basin. Zn and PCBs were positively correlated ($r= 0.60$; $p< 0.01$) between each other, and with organic carbon ($r\geq 0.70$; $p< 0.01$). These correlations suggest a similar distribution of these compounds in the Adriatic Sea, probably driven by the same transport mechanisms and indicating terrigenous input. Trace metals concentrations were above the background levels for the Adriatic Sea (Zn=85; Pb=18;Cu=35 mg kg^{-1}). These elements, mainly Pb and Zn, have a large anthropogenic component in this marine basin, coming from atmospheric inputs and from industrial tailings and wastes. Finally, due to Adriatic Sea semi-enclosed character, metals and PCBs accumulation in the northern part could represent the influence of human activities, which could, in turn, alter the environmental quality status of this European sea.

WE078

Do persistent and mobile organic contaminants fulfil the definition of substances of very high concern owing to their equivalent level of concern defined by REACH

S. Hale, NGI; H. Arp, NGI / Environmental Engineering; L. Vierke, Federal Environment Agency UBA / Section IV Chemicals; M. Neumann, Federal Environment Agency (UBA) / Section IV Chemicals

In Article 57 of the REACH Regulation (1), criteria are given in order to identify substances of very high concern (SVHCs). Within this definition SVHCs can be carcinogens, mutagens and/or reproductive toxicants (CMRs as defined in article 57 a-c) as well as persistent, bioaccumulative and toxic (PBT/vPvB, as defined in article 57 d-e) substances. Furthermore, Article 57 provides a definition of compounds that should be identified as SVHC based upon their equivalent level of concern to CMR or PBT substances and having probable serious effects to human health or the environment (article 57f). The definition of "equivalent level of concern" is open to interpretation. This work investigates whether persistent and mobile organic contaminants (PMOCs) fulfil the requirements and thus can be considered as compounds possessing an equivalent level of concern. In order to investigate whether the requirements are fulfilled, we will focus on which properties of PMOCs could lead to a probable serious effects to human health or the environment at an equivalent level of concern to CMR or PBT substances. This in part is based on the ability of some PMOCs to reach water treatment plants, to resist treatment processes and thus to reach drinking water supplies enabling exposure to humans and thus possible adverse effects on human health. A literature review will identify PMOCs that have reached drinking water supplies based on normal use and not through accidental spillage. One prominent example is that of perfluorinated compounds used historically in aqueous film forming foams to put out fires and which has resulted in contamination of drinking water sources in Sweden and has impacted water supplies in Norway. These case studies will provide a line of evidence to define scientifically why PMOCs are hazardous and will then be used in the context of Article 57f to assess whether PMOCs are of equivalent level of concern and have probable serious effects on human health or the environment. (1) ARTICLE 57: Substances to be included in Annex XIV, TITLE-VII: AUTHORISATION CHAPTER-1: Authorisation requirement

WE079
Fast and accurate screening of small polar organics in the water cycle with UHPLC-QTOF
V. Albergamo, University of Amsterdam/IBED Institute; R. Helmus, University of Amsterdam IBED Institute / IBED; P. de Voogt, University of Amsterdam / IBED
The contamination of water sources with anthropogenic polar organic micropollutants (MPs) raises ecotoxicological and toxicological concern. Polar substances can be highly water soluble, highly mobile and can accumulate in aquatic ecosystems when they are not completely removed by natural barriers (e.g. riverbank filtration) and conventional water treatment. Their chemical identities and concentrations observed in the water cycle are constantly changing as a result of societal and climate change, hence reliable tools for the screening of emerging contaminants are needed. The characterization of organic pollutants is essential to assess the potential ecotoxic and toxic effects of individual chemicals and mixtures. In the present work, we developed an analytical method for the screening of small polar MPs with UHPLC-ESI-QTOF-MS. The method was applied to a selection of chemicals having low molecular weights (pH7< 4.5). The selection of the analytes was based on literature data and consisted of 25 polar MPs that have been observed in groundwater, drinking water, and that are not fully removed by reverse osmosis. Liquid chromatography was performed with a core-shell biphenyl stationary phase featuring specific polar retention mechanisms and 100% aqueous stability. Various mobile phase solvents and modifiers were tested, and optimal peak shape and sensitivity were achieved with a fast 7-min linear gradient of 0.05% acetic acid (A) and methanol (B). Water samples were extracted, purified and concentrated using optimized solid phase extraction methodology with hydrophilic lipophilic balanced (HLB) sorbent. The robustness of combining SPE with the UHPLC-ESI-QTOF-MS method was tested with groundwater, drinking water and demi water samples spiked with 50 ng/L analytes prior to extraction. Satisfactory recoveries resulted in LOQs within the sub-ng/L to ng/L range for both matrices. Identification with a high certainty was supported by HR mass spectra. The method was incorporated in a novel software tool for automated target and suspect screening, which allowed fast identification and quantification based on HRMS data. Combining our analytical method with automated screening proved to be an efficient approach to analyze trace levels of a broad range of polar MPs, and can contribute to the characterization of toxic and ecotoxic profiles in the water cycle.

Diffusion of a dechlorinated metabolite of terbuthylazine in Northern Italian groundwaters
S. Valsecchi, Water Research Institute - Italian National Research Council IRSA-CNR; S. Polesello, M. Rusconi, Water Research Institute - Italian National Research Council IRSA-CNR / Water Research Institute; M. Mazzoni, Water Research Institute - Italian National Research Council IRSA-CNR; O. Longoni, A. Sala, BrianzAcque s.r.l
During a screening campaign on groundwaters used as a source of drinking waters in the area North of Milano, an anxiolytic drug, called Mebikar, has been found in some wells. The origin of this molecules has not been yet identified, but during the tests carried out by high resolution mass spectrometry (HRMS) for confirmation purpose an isobaric compound (MW 198.222360 g/mol and molecular formula $C_8H_{14}N_4O_2$)has been determined in many groundwater samples. The interpretation of the mass spectrum allowed to identify the compound as 4-(*tert*-butylamino)-6-hydroxy-1-methyl-1,3,5-triazin-2(1*H*)-one, which is a described dechlorinated metabolite of the erbicide terbuthylazine, also known as LM6. Other structurally related metabolites were tentatively identified by retrospective analysis via HRMS. These metabolites have been described in the registration document from Syngenta and in the ECHA dossier, but they are neither described in the scientific literature neither registered in CAS. Because ECHA underlined the need for reliable analytical methods for these polar terbuthylazine metabolites, we developed an HPLC-HRMS method based on an Orbitrap system which allowed to determine these compounds in groundwaters and treated drinking waters. In order to characterise the compounds and their diffusion in Northern Italian groundwater we carried out a wide monitoring campaign which highlighted the large diffusion of these compounds. The diffusion has been related to specific soil uses, with special regards to maize cultivation. The results of the occurrence study with literature toxicological data allowed to draft a preliminary risk assessment for these metabolites which should contribute to the derivation of threshold limits for groundwater.

WE081
Screening of chemical pesticides in Swedish surface water and groundwater
G. Boström, Swedish University of Agricultural Sciences (SLU) / Centre for Chemical Pesticides; B. Lindström, Swedish University of Agricultural Sciences / Centre for Chemical Pesticides; M. Gönczi, SLU / Centre for Chemical Pesticides; J. Kreuger, Swedish University of Agricultural Science / Centre for Chemical Pesticides
In early 2015 the Swedish EPA was commisioned by the Government to carry out a screening for environmental pollutants including chemical pesticides. A broad screening of chemical pesticides in surface water and groundwater in areas with high agricultural intensity in southern Sweden was therefore requested. This screening program was carried out by the Centre for Chemical Pesticides at the Swedish University of Agricultural Sciences during 2015. The screening was aimed at achieving a better surface coverage compared to the regular national monitoring program and consisted of extensive sampling of both surface water and groundwater. Surface water samples were collected from 46 different sites during May-October, half of the sites were sampled on 5 occasions and half of them on 1-3 occasions. The groundwater sampling was focused on private wells as previous monitoring has indicated that these are more sensitive to pesticide contamination than municipal groundwater wells. The sampling was done in 54 private wells and 18 municipal water works (incoming ground water) on one occasion. Surface water and groundwater samples were analyzed for 131 and 108 different pesticides, respectively. The results include information on which pesticides are the most frequently detected in Swedish surface water and groundwater, as well as on exceedances of the drinking water limit or ecotoxicological guideline values. The results are also analyzed in the light of collected metadata to explore potential correlations with elevated concentrations of pesticides. For surface water correlations with the portion of agricultural land and the size of the drainage area are analyzed. For groundwater relationships to the depth of the well, the distance to agricultural fields and the age of the well are examined. Correlations are also made with well water concentrations of nitrate and *E. coli* as possible signs of well vulnerability. The preliminary results from the screening program are largely consistent with results seen within the regular, spatially limited, national monitoring program. The final results are currently being analyzed and will be reported to the Swedish Government by mid-March 2016. A comprehensive evaluation of pesticide occurrence in Swedish waters will be available for poster presentation.

Antibiotics and Antibiotic Resistance in the Environment: Ecological Fate and Effects, Resistance Development and Implications for Human Health (P)

WE082
Chronic toxicity of cephradine and cefadroxil in Daphnia magna and freshwater fish Oryzias latipes
B. Kim, Department of Environmental Health; K. Ji, Yongin University
Pharmaceuticals in the environment are of growing concern for their potential consequences on human and ecosystem health. Cephradine and cefadroxil, two cephalosporin antibiotics for animals, have been frequently detected in freshwater environment, however their toxicological information is very limited. In the present study, the adverse effects of chronic exposure to cephradine and cefadroxil were evaluated using *Daphnia magna* and *Oryzias latipes*. Chronic toxicity tests with *D. magna* was conducted as outlined in the OECD test guideline 211. *D. magna* were exposed to cephradine and cefadroxil (0, 6.25, 12.5, 25, 50 and 100 mg/L) for 21 d. Fish embryos were exposed to cephradine and cefadroxil (0, 0.001, 0.01, 0.1, 1 and 10 mg/L) for 30 dph. Thyroxine (T4) levels in juvenile fish were measured using enzyme-linked immunosorbent assay (ELISA), and transcriptions of 8 genes in the hypothalamic-pituitary-thyroid (HPT) axis (*trh*, *trhr*, *thrα*, *thrβ*, *tshr*, *tg*, *dio1*, *dio2*) were also measured using real-time polymerase chain reaction (qPCR). The no observed effect concentrations (NOECs) based on the endpoints of survival, reproduction, and growth in *D. magna* exposed to cefadroxil and cephradine were 100 mg/L, except growth NOEC for cephradine (50 mg/L). Survival and body length in juvenile fish were significantly decreased at ≥0.1 mg/L cephradine. While no significant change was observed in T4 hormone, the transcriptions of *tshr* and *tg* genes were significantly altered by exposure to cephradine. These results support that cephradine has the potential to inhibit the normal growth in macroinvertebrate and early-life stage fish, and these were accompanied by an inhibition of mRNA expressions related to thyroid hormone endocrine system. Concentrations of the pharmaceutical studied that have been reported to occur in rivers of Korea are much less than the

thresholds for effects on the endpoints studied here. Further investigations on endocrine disruption potential in aquatic organisms exposed to environmentally relevant concentrations are recommended. \n *Acknowledgement* – This study was supported by National Research Foundation of Korea (Project no. NRF-2013R1A1A1061684).

WE083

Evaluation of potential effect of veterinary pharmaceuticals in concentrated animal feeding operation (CAFO) of Korea

B. Kim, Department of Environmental Health; C. Kim, Seoul National University / School of Public Health; H. Kang, Seoul National University / Environmental Health Sciences; S. Lee, Seoul National University / School of Public Health; B. Kwon, Yongin University / Department of Environmental Health; Y. Kho, Eulji University; K. Choi, Seoul National University / School of Public Health; K. Ji, Yongin University

There is a growing concern about the effects of pharmaceuticals and other pollutants from concentrated animal feeding operation (CAFO), since farm wastes often reach the environment without appropriate treatment. However, limited information is available on monitoring of antibiotic residues and potential risks in water environment around the animal farms. In the present study, potential toxicity on steroidogenesis in water extraction samples were evaluated using H295R cell lines. Measurement of veterinary pharmaceuticals and ecological risk assessment were also performed. Water samples were collected from five locations in a stream that runs alongside a CAFO area in Yongin, Korea. Several upstream and downstream locations were sampled for ambient water during June (low-flow) and August (high-flow), 2013. Total 12 pharmaceuticals (acetaminophen, cephradine, ibuprofen, mefenamic acid, six sulfonamides, and two tetracyclines) were evaluated using HPLC-MS/MS. The effects on the hormone production and expression of mRNAs involved in steroidogenesis were determined with H295R cell bioassays. Hazard quotients were derived from the highest measured environmental concentrations and predicted no effect concentrations. The pharmaceutical concentrations measured near CAFO area were greater than those in upstream or far downstream areas, suggesting that elevated pharmaceutical concentrations in waters are associated with activities of CAFO. Except one sampling area, the level of detection of the target pharmaceuticals were decreased in the high-flow season. However, greater production of 17β-estradiol (E2) was observed in the samples collected during the high-flow season, suggesting that possibly non-point source contaminants other than pharmaceuticals from CAFO may also cause endocrine disruption. Hazard quotients for several pharmaceuticals including acetaminophen exceeded unity, suggesting potential ecological effects in this area. *Acknowledgement* – This study was supported by National Institute of Environmental Research of Korea.

WE084

Effects of temperature, genetic variation and species competition on the sensitivity of algae populations to the antibiotic enrofloxacin

A. Rico, Wageningen University / Environmental Risk Assessment Team; W. Zhao, F. Gillissen, Wageningen University / Aquatic Ecology and Water Quality Management Group; M. Lurling, Wageningen University / Aquatic Ecology Water Quality; P. van den Brink, Alterra and Wageningen University / Aquatic Ecology and Water Quality Management Group

Primary producers, particularly cyanobacteria, are amongst the most sensitive organisms to antibiotic pollution in aquatic ecosystems. In this study we investigated the effects of the fluoroquinolone antibiotic enrofloxacin on the cyanobacterium *Microcystis aeruginosa* and the green algae species *Scenedesmus obliquus*. The toxicity of the antibiotic was investigated in the laboratory under different temperature conditions (20 and 30°C) and using three different strains of each species. Furthermore, it was investigated how antibiotic pollution affects the competition between *M. aeruginosa* and *S. obliquus*. The competition experiment was performed using three competition treatments, defined as density ratios (i.e. initial bio-volume of 25/75%, 10/90% and 1/99% of *S. obliquus*/*M. aeruginosa*, respectively), one *S. obliquus* control (100% *S. obliquus*) and one *M. aeruginosa* control (100% *M. aeruginosa*), and four different ENR concentrations (i.e., control, 0.01, 0.05 and 0.10 mg/L). In all experiments, growth inhibition based on cell number, bio-volume, chlorophyll-a concentration, as well as PSII efficiency were used as evaluation endpoints. In the majority of the cases PSII efficiency was found to be the most sensitive endpoint, followed by growth inhibition based on cell number. *S. obliquus* was found to be slightly more sensitive at 20°C than at 30°C (EC50-72h of 38 and 41 mg/L, respectively), whereas an opposite trend was observed for *M. aeruginosa* (0.047 and 0.037 mg/L, respectively). Differences in EC50s between strains were within a factor of two. The competition experiment showed that *M. aeruginosa* growth can be significantly reduced at 0.01 mg/L in the presence of *S. obliquus* at a density ratio of 25/75% *S. obliquus*/*M. aeruginosa*. The results of this study confirm the high sensitivity of cyanobacteria to antibiotics and show that temperature and genetic variation can influence their response to them. Furthermore, the results of the competition experiment suggest that the structure of primary producer communities can be affected at antibiotic concentrations close to those that have been monitored in the environment.

WE085

Assessing sensitivity to antibiotics in freshwater cyanobacteria and microalgae

G. Le-Page, Uiversity of Exeter / Biosciences; M. Trznadel, L. Gunnarsson, University of Exeter / Biosciences; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; C. Tyler, Biosciences College of Life and Environmental Sciences

Cyanobacteria (CB) and microalgae (MA) play fundamental roles in primary production and nutrient-cycling in aquatic systems. Disruption to these communities through chemical exposure can therefore have far-reaching ecosystem consequences. Antibiotics (AB) cause toxicity to prokaryotic cells. Although there are examples where the drug targets appear to be evolutionarily conserved in some eukaryotes, for example in MA that have chloroplasts, the vast majority of the targets are not conserved. The likely consequence is that eukaryotes such as metazoans will not show adverse effects to ABs at exposures of environmental relevance. Environmental risk assessment (ERA) for the registration of AB requires ecotoxicity testing with daphnia and fish but encourages testing for a single species of CB for prokaryotes, as an alternative to the test with a MA. Current ERA of ABs therefore may not be protective for prokaryotes as a whole. Given their importance to ecosystem services we argue that wider understanding on the effects of ABs on prokaryotes and algae is required. It has been suggested that the ERA of ABs should evaluate risk of antibiotic resistance and the predictive no effect concentration may be based on minimum inhibition concentrations (MIC) in clinically relevant bacteria. Increased knowledge regarding differences in species sensitivity will help ensure MIC based ERA will be protective for environmentally relevant bacteria. On the premise that knowledge of variation in species sensitivity to antibiotics in CB and MA is important to better inform current ERA practice for the protection of prokaryotes and algae, we investigated the effects of 3 ABs with different MOAs (ciprofloxacin, sulfamethoxazole and cefotaxime) on 3 CB and on 2 MA. We set out to determine whether one species of CB is representative of a diverse class of taxa and across different MOAs. Inhibition of population growth (a standard regulatory endpoint), expression of relevant target genes (via qPCR) changes in the cell phenotype (through TEM), and bioavailability were for each species and AB studied. Significant differences in the growth rate for the different AB exposures were observed between the CB and MA. Moreover, the three CB species varied in their sensitivity to the AB effects by up to one order of magnitude. Data will be presented illustrating how sensitivity in responses relates to bioavailability and pharmaco-dynamic properties of each antibiotic.

WE087

Selection for Antibiotic Resistance in Complex Microbial Communities

I. Stanton, University of Exeter; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; W. Gaze, The University of Exeter / Medical School

Antibiotics have been regularly used since the 1900's to treat bacterial infections and have revolutionised modern medicine. However, after development of a particular antibiotic class, resistance genes to counteract the effect of the antibiotic have always emerged. Therefore, there is potential to return to a pre-antibiotic era where treating bacterial infections becomes impossible. Antibiotics are found throughout the environment. They are naturally produced by certain bacterial species; however human activity also leads to the release of measurable quantities into environmental systems. Release into the environment can occur through use of antibiotics in the clinic, as the more stable compounds are excreted into water systems. However, other sources include through use of antibiotics therapeutically and as growth promotors in agriculture, release from pharmaceuticals and use in personal care products. Antibiotics in the environment have the potential to exert a selective pressure on environmental bacteria causing resistance. Recently (2015), antibiotics have been added to the priority substances watch list of the Water Framework Directive for the first time. Macrolides, the group added, have been found in concentrations of up to 90μg/L within water environments. This study will investigate the evolution of macrolide resistance in aquatic systems by studying the genetic mechanisms of macrolide resistance in complex microbial communities and studying experimental evolution of macrolide resistance using culture independent and next generation sequencing methods.

WE088

Minimum inhibitory concentrations and antibiotic resistant genes in the freshwater cyanobacteria Planktothirx agardhii

E. Dias, National Institute of Health Doutor Ricardo Jorge / Department of Environmental Health; M. Oliveira, National Institute of Health Doutor Ricardo Jorge / Department of Health Sciences; D. Jones-Dias, Infectious Diseases / Department of Infectious Diseases; V. Manageiro, National Institute of Health Doutor Ricardo Jorge / Department of Infectious Diseases; C. Churro, National Institute of Health Doutor Ricardo Jorge / Department of Environment Health; V. Vasconcelos, Faculty of Sciences   and CIIMAR - Porto University; E. Ferreira, National Institute of Health Doutor Ricardo Jorge / Department of Infectious Diseases; M. Caniça, National Institute of Health / Department of Infectious Diseases

Objectives: Cyanobacteria are ubiquitous prokaryotes in aquatic ecosystems and although they can be exposed to antibiotics and antibiotic resistant bacteria, their role on water resistome was never investigated. *Planktothrix agardhii* is one of the

most common cyanobacteria species in Portuguese freshwater reservoirs, often exhibition long residence time in those reservoirs. This work aimed to evaluate the antibiotic susceptibility patterns and resistance mechanisms in *P. agardhii* in order to assess their putative contribution to the global pool of resistance determinants in freshwater. **Methods:** We investigated 8 strains of *P. agardhii*, previously isolated from different freshwater reservoirs. The antibiotic susceptibility was evaluated by a microdilution method previously adapted for cyanobacteria, against beta-lactams, aminoglycosides, quinolones, trimethoprim and tetracycline. Minimum inhibitory concentrations (MIC) were determined according to cell density (DO, 450nm) and microscopic examination of cultures integrity. All strains were searched for antibiotic resistance genes and class 1, 2 and 3 integrons by PCR/sequencing. **Results:** The results showed that *P. agardhii* is not susceptible to trimethoprim and quinolones within the tested concentrations (0.0015-1.6 mg/L). However, the cell growth is strongly inhibited by amoxicillin (median MIC value of 0.1mg/L). The other antibiotics presented the following median MICs: ceftazidime, 1.6 mg/L; ceftriaxone, 0.8 mg/L; tetracycline, 0.4 mg/L; kanamycine, 0.2 mg/L and gentamicine, 0.1mg/L. None of the *P. agardhii* strains exhibited genes associated with trimethoprim and quinolones resistance, which suggests that these cyanobacteria are intrinsically non susceptible to this antibiotics. Conversely, genes associated with streptomycin (*str*A-*str*B) and sulfonamide (*sul*1) resistance, as well as a 1-type integron, were detected in three of the strains. These strains were isolated from the freshwater reservoirs where *Planktothrix* blooms are frequent and. This suggests that the presence of a common antibiotic resistant determinant in *P. agardhii* might be a result from a similar selective pressure within those reservoirs. **Conclusions:** The presence of antibiotic resistance genes and integrons, as well as the reduced susceptibility to antibiotics, suggest that cyanobacteria may play a role on freshwater resistome and eventually contribute to the dissemination of antibiotic resistance in freshwater environments.

WE089

Antimicrobial susceptibility of E. coli isolates from meat industry wastewater

M. Stosic, Faculty of Technical Sciences, Novi Sad / Department of Environmental Engineering and Occupational Safety and Health; D. Cucak, University of Novi Sad Faculty of Sciences; S. Kovacevic, University of Novi Sad Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; M. Perovic, Jaroslav Černi Institute for the Development of Water Resources; J. Radonic, Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; M. Turk-Sekulic, University of Novi Sad / Department of Environmental Engineering and Occupational Safety and Health; M. Vojinovic MIloradov, Faculty of Technical Sciences University of Novi Sad / Department of Environmental Engineering and Occupational Safety and Health; D. Radnovic, University of Novi Sad Faculty of Sciences

Wastewater originating from the meat processing industry is characterized by the high presence of organic waste load and potentialy pathogenic microorganisms.*This study consisted of four sampling campaigns, during four seasons in 2013 and 2014.Wastewater was collected from three meat processing plants in the Province of Vojvodina, Republic of Serbia.* The aim of this research was to determine the posible resistance of isolated *E.coli* strains to selected antibiotics.The evaluation of the antimicrobial susceptibility was performed on 37 strains of *E.coli* to 9 different antibiotics.Antibiotics, as emerging pharmaceuticals, used for susceptibility testing were: ampicillin, cefotaxime, ciprofloxacin, chloramphenicol, gentamicin, nalidixic acid, streptomycin, tetracycline, and trimethoprim-sulfamethoxazole.Monitoring of antimicrobial resistance in commensal bacteria *E.coli* is of great significance because this species is commonly present in animal faeces, and can often acquire conjugative plasmids from other present enteric bacteria, thus serving as a valuable reservoir of resistance genes which can be transferred to other bacteria present in same environment. From a total of 37 strains of *E.coli*, a moderate degree of resistance was shown to tetracycline (37.83%); low degree of resistance to ampicillin (21.62%), streptomycin (24.32%), trimethoprim-sulfamethoxazol (18.92%) and nalidixic acid (16.22%); a very low to: chloramphenicol (13.51%), ciprofloxacin (2.7%), gentamicin and cefotaxime (0.0%). Ten of the tested *E.coli* strains (18.92%) were multidrug-resistant. Antibiotics used in this experiment are present on the NORMAN list of emerging substances of concern, since they are most frequently detected in aquatic environment. Due to their detectable presence in the environment, we have to be very careful because it increases the possibility for antimicrobial ressistance in microorganisms which have been in contact with antibiotic residues. High public pressure considering the consequences of mass appearance of multi-resistant bacterial strains that have spread from the animals to humans, managed to significantly reduce the use of antibiotics, especially as growth promoters.Serbia also adopted this EU legislation but more stringent control of law implementation is needed. **Acknowledgement**This work has been done within the NATO project (Ref.984087), and it has also been financially supported by Ministry of Education and Science, Republic of Serbia (Project No.46009).

Presence of multiple antibiotic resistant Enterococcus spp. harbouring virulence genes in WWTP effluent and receiving water systems in the North West Province, South Africa

L.G. Molale, North West University (Potchefstroom Campus) / Microbiology; C.C. Bezuidenhout, North - West University / Unit for Environmental Sciences and Management

Faecal contaminants from poor operating waste water treatment plants pose a health risk to humans and animals. The latter is heightened when multiple antibiotic resistant bacteria harbouring virulence genes are present. The aim of the current study was to determine the antimicrobial resistance patterns and presence of virulence genes in *Enterococcus* spp. isolated from the final effluent of three municipal wastewater treatment plants and receiving water systems in the North West Province, South Africa. Sixty three *Enterococcus* isolates were isolated and antimicrobial susceptibility test performed on all isolates. Antibiotic inhibition zone diameter data was subject to cluster analysis. The cluster composed of *Enterococcus* spp. from all WWTPs final effluent was predominated by *E. faecalis* spp. followed by *E. faecium* and *E. hirae* spp. Whereas the cluster composed of *Enterococcus spp.* from downstream sites of receiving water systems was predominated by *E. gallinarum, E. casseliflavus* and *E. mundtii*. All 63 *Enterococcus* spp. were screened for the presence of five virulence determinants (*asa1, cylA, esp, gelE* and *hyl*). All five virulence genes were detected and six multi-virulence profiles observed. Analysis of the antimicrobial susceptibility of the 63 *Enterococcus* isolates revealed that resistances to Ampicillin (67%), Vancomycin (62%), Tetracycline (58%), Penicillin (52%) and Erythromycin (51%) were most frequent. Sixty eight percent of the screened *Enterococcus* spp. were resistant to three or more antibiotics. Seventy six of the screened *Enterococcus* isolates resistant to multiple antibiotics had plasmids. Differences in MAR phenotypes were observed for all profiles pre- and post-plasmid curing with lower resistance profiles post plasmid curing. This study has demonstrated that *Enterococcus* spp. harbouring virulence factors and plasmids that mediate multiple antibiotic resistance are present in WWTPs final effluent and receiving water systems that support a variety of social needs in South Africa. Thus, it is recommended that *Enterococcus* spp. be used as an additional faecal indicator in conjunction to *E. coli*. **Keywords:** *Enterococcus* spp.; WWTP final effluent; multiple antibiotic resistance; virulence genes

WE091

Antibiotic-resistant bacteria from air samples collected in nursing homes

V. Salgueiro, V. Manageiro, National Institute of Health Doutor Ricardo Jorge / Department of Infectious Diseases; D. Jones-Dias, Infectious Diseases / Department of Infectious Diseases; M.M. Cano, National Institute of Health Doutor Ricardo Jorge / Department of Environmental Health; E. Ferreira, National Institute of Health Doutor Ricardo Jorge / Department of Infectious Diseases; M. Caniça, National Institute of Health / Department of Infectious Diseases

Introduction Antibiotic resistance is currently a worldwide public health problem that can include diverse mechanisms and bacterial species. The understanding and monitoring of such phenomena is essential to avoid further dissemination. The main aim of this study was the characterization of antibiotic resistance mechanisms in bacterial strains collected in air samples from nursing homes and compare them with clinical samples isolated from the same geographic area. **Materials and methods** Air samples were collected from bedrooms, living rooms and outdoor of 4 nursing homes located in Lisbon, Portugal. Screening of antimicrobial susceptibility of 18 Gram-negative (5 *Acinetobacter* spp., 1 *Klebsiella oxytoca*, 4 *Pantoea* spp., 7 *Pseudomonas* spp., 1 *Sphingomonas paucimobilis*) and 12 Gram-positive (3 *Micrococcus luteus*, 3 *Staphylococcus* spp.) isolates was performed by disk diffusion method. Different antibiotic resistant genes were searched by PCR. PFGE was used to evaluate clonality between *K. oxytoca* isolated from the air environment and other strains from clinical origin. **Results and discussion** The majority of strains were susceptible to all antibiotics tested. Among beta-lactam antibiotics, reduced susceptibility to cefoxitin was detected in *Staphylococcus capitis*, through expression of the *mecA* gene, and to ampicillin, piperacillin and piperacillin-tazobactam in 1 *K. oxytoca* expressing a bla_{OXY-5}-type beta-lactamase. Nonsusceptibility to meropenem and piperacillin-tazobactam was observed in 2 *Pseudomonas putida* however no antibiotic resistance gene was detected. Regarding quinolones, non-susceptibility was found in 1 *S S. capitis*, 2 *Staphylococcus haemolyticus*, and 1 *K. oxytoca*. The molecular characterization of the *mecA*-positive *S. capitis* from the nursing homes and from a hospital within the same region suggests a potential dissemination of strains between these two environments. The genetic relatedness of *K. oxytoca* from nursing homes (n=1) and clinical isolates (n=9) recovered within the same region, allowed to conclude that they were not genetically related. **Conclusions** Globally, nursing homes environments may act as complementary reservoirs of antibiotic resistant bacteria and antibiotic resistance genes. Thus, a better understanding of the antibiotic resistance mechanisms and dissemination pathways in other reservoirs than human is essential to control its emergence and spread.

WE092

Antimicrobial susceptibility and integron diversity in organic and conventionally grown fruits and vegetables

D. Jones-Dias, Infectious Diseases / Department of Infectious Diseases; I.B.

Moura, E. Ferreira, National Institute of Health Doutor Ricardo Jorge / Department of Infectious Diseases; M. Caniça, National Institute of Health / Department of Infectious Diseases

Introduction: During growth and harvesting fresh produce can become contaminated not only with environmental, but also pathogenic bacteria from animal and human sources. This study aimed to characterize the antibiotic resistant bacteria gathered from organically and conventionally grown fruits and vegetables, and to characterize the diversity of class 1, 2 and 3 integrons detected. **Methods:** Between 2013 and 2014, one conventionally and one organically produced batch of six fruits and vegetables were purchased at retail stores. Products were processed as follows: 50g of product was selected at random without washing or peeling, diluted and homogenized. The selection of resistant Gram negative bacteria was performed in VRBG plates containing ten different antibiotics separately. The isolates were identified through the amplification of the 16S rDNA. Antimicrobial susceptibility was assessed by disc diffusion method using EUCAST guidelines. All isolates were investigated for the presence of class 1, 2 and 3 integrons, through PCR amplification, and their variable region was explored by a strategy of Next Generation Sequencing. **Results:** A total of 333 isolates showing nonsusceptibility to, at least, one antibiotic were collected among 144 samples. Among others, *Enterobactericeae* (n=184), *Moraxellaceae* (n=88), *Pseudomonadaceae* (n=36), were detected. Nonsusceptibility was mainly identified among β-lactam antibiotics for *Enterobactericeae* recovered from conventionally produced samples (45.1%); overall, cefoxitin was the most ineffective antibiotic (19.6 % for organic and 26.6% for conventionally grown produce). The molecular screening for the integrase-encoding gene showed the presence of eight isolates with class 1 (2 *Enterobacter*, 2 *Escherichia*, 1 *Morganella*, 2 *Acinetobacter* and 1 *Pseudomonas* spp.), three isolates with class 2 (1 *Escherichia* and 2 *Raoutella* spp.), and one isolate with class 3 integrons (*Klebsiella* spp.). The integrons revealed a variety of gene cassettes conferring nonsusceptibility to different classes of antibiotics. **Conclusion:** Resistance was more frequent in the products grown in close contact with the soil. Besides environmental bacteria, many pathogenic agents were also detected. Lettuce was significantly associated with the existence of class 1 and 2 integrons regardless of the origin. Both organic and conventional produced fruits and vegetables may constitute potential sources of resistant bacteria and of integrons.

The intensive uses of antibiotics (AB) in human and veterinary medicines contributed to widespread environmental contaminations, through the wastewater discharges and the recycling of organic wastes (OW) as soil amendments. While the occurrence and persistence of AB in the environment have become major environmental and human health issues, their ecotoxicological impacts are not well understood. AB inhibit active microorganisms and therefore can represent an important risk for the environment, especially for soil microbial functions (organic matter degradation, nutrient recycling). However, these side-effects depend on the bioavailability of AB. Organic matter quality is a key environmental factor influencing soil dissipation processes of AB which can control the bioavailability. Our objectives were to investigate the effects of the sulfamethoxazole (SMX) on microbial nitrogen transformations in relation with AB bioavailability in soil. A dose-effect approach was performed with different doses of SMX supplied to two different OW (compost of sewage sludge / green waste (SGW), farmyard manure (FYM)) before their application to soil. The final doses of SMX in soil microcosms ranged from 0,022 to 2,22 mg kg^{-1}_{dw}, with control soils amended with OW without SMX. Nitrogen forms, potential nitrification and denitrification activities were determined in soils, after 7, 28 and 84 days following amendments. Also, the total amount of SMX and the chemically available fraction were extracted respectively with organic and aqueous solutions and then quantified by UPLC-MS/MS. At these low doses, only nitrification activity was adversely impaired by SMX, following a dose-response pattern, in soils amended by SGW. Actually, as the SMX is a bacteriostatic antibiotic, the effects were stronger for growing microbial populations, such as the nitrifiers which are largely promoted by the high levels of NH_4^+ in SGW amended soils compared to FYM amended soils. The chemical assessment of SMX availability did not show strong differences between the SGW or FYM amended soils. However, throughout the experiment, the decrease of SMX availability was in accordance with a partial recovery of soil nitrification in SGW amended soils. Nitrification is a sensitive indicator of AB effects on soil microbial functioning. Its recovery after AB exposure may be explained by a strong decrease in the chemical availability and consequently in the bioavailable fraction of AB for microorganisms

WE094

Bacterial community structure and biogeochemical activity in soil irrigated with treated wastewater in Tunisia

C. Michel, BRGM; O. Mahjoub, INRGREF; L. Lalande, BRGM; a. Mauffret, BRGM / Environmental biogeochemistry and water quality

In semi-arid regions, agricultural activity relies on water availability. For instance, during the dry season, from June to September in Nabeul region (Tunisia), the irrigation of citrus trees with treated wastewater is an old practice.Conjunctive use of groundwater (salinity 2-5 g/L)with treated wastewater may alsotake place. In this work, we focus on the effect of emerging substances, possibly present in the irrigation water, on soil bacteria diversity and function. Three irrigated plots were selected based on the type of irrigation water: treated wastewater, groundwater, and treated wastewater and groundwater together. Soils were sampled at 0-5 and 5-20 cm depth in June, July, August, and October 2015. Protein production (3-H leucine incorporation) and mineralization of different carbon sources (Biolog) were measured to assess activity of the microbial community in soil samples. Abundance of the universal marker (16S rRNA) and of nitrate-reducing bacteria (*narG* and *napA*) was assessed by qPCR. Presence of the ammonium oxidizing bacteria was assessed by the *amoA* gene detection by PCR. Biodiversity was assessed with a fingerprinting technique (CE-SSCP). Forty emerging substances, including human and veterinary antibiotics, were assessed in groundwater and treated wastewater by HPLC/MS-MS. Preliminary results showed that caffeine, carbamazepine and its metabolite 10,11-epoxycarbamazepine, ketoprofene, ofloxacine, propranolol hydrochloride, and sulfamethoxazole were quantified in both ground and treated waters at concentration higher by 2 orders of magnitude in the treated water (n=4). The results allowed determining whether soil microbial communities are affected by irrigation water and their implication in biogeochemical cycle.

WE095

Removal Characteristics and Mechanism of Antibiotics in the Constructed Wetlands

Y. Choi, Seoul National University / Department of Environmental Health Sciences; M. Kim, Environmental Health / Department of Environmental Health Sciences; K. Zoh, Seoul National University / Department of Environmental Health

The occurrence and removal of antibiotics (sulfamethoxazole (SMZ), sulfathiazole (SFI), sulfamethazine (SMA), trimethoprim (TMP), tetracycline (TC), oxytetracycline (OTC), chlortetracycline (CTC), and enrofloxacin (EFX)) using a constructed wetland (CWs) for treating livestock wastewater were investigated. The levels of antibiotics in the effluents of the CWs were in the order of CTC, SFI, SMZ, SMA, TMP, OTC, EFX and TC, ranging from 47.98 to 6834.66 µg/L, respectively. There was an inverse correlation ($p < 0.0493$) between the removal of sulfonamide group (SMZ, SFI, and SMA) and tetracycline group (TC, OTC, and CTC) antibiotics in the effluents of the CWs, indicating that sulfonamide-type antibiotics were more effectively removed in the CWs. Sulfonamide-type antibiotics have higher pKa values, resulting in more effective adsorption into negatively charged soils through electrostatic interaction. Therefore, the physicochemical properties (e.g., molecular weight, pKa value, ionic bonds, and functional groups) can be the important factors in CWs. Sunlight photo-degradation experiment showed that EFX was effectively removed (70%) compared to other antibiotics. The microcosm adsorption experiments using wetland soils under biotic and abiotic conditions showed that antibiotics in biotic system were more effectively removed than abiotic systems, indicating that soil-mediated microbial degradation is a major removal mechanism. The microcosm adsorption experiments using wetland plants (Phragmites australis) showed that the biotic system also removed sulfonamide-type antibiotics more effectively compared to the abiotic system. Our results suggest that the removals of antibiotics in the CWs are mainly mediated by biodegradation and adsorption onto soil and plants. This study implies that the CW system can be used for the removal of antibiotics for seondary livestock wastewater treatment.

WE096

Direct Photolyses of Ofloxacin and Sulfamethylthiazole

S. Chen, College of Chemistry and Environmental Engineering; S. Yang, Y. Lin, Hanshan Normal University / College of Chemistry and Environmental Engineering

Due to large scale uses in animal husbandry and aquaculture, ofloxacin (OFL) and sulfamethylthiazole (SMZ) are representative antibiotics found in the surface waters in China, and photolysis is considered as an important pathway for their degradation in nature. In this study, the direct photolysis of OFL and SMZ under simulated sunlight (SL) and mercury vapor lamp (MPL) were investigated with an Agilent Technologies 1260 Infinity HPLC as the analytical tool. Depending on the light intensity of the SL and MPL, typical half-lives of these two synthetic antibiotic compounds were in the range of minutes and the reactions seemed to follow first order kinetics. Mixed aqueous solution of OFL and SMZ was exposed to SL and MPL, respectively, and it was found that SMZ underwent faster photolysis than OFL, but the rates of degradation were slower in comparison with their single component individual rates. The presence of hydrogen peroxide or molecular oxygen in the aqueous solutions seemed to accelerate the photolysis for both the OFL and SMZ. MPL emitted more UV radiation than the SL and tended to expedite the photolysis. The diode array detector of the HPLC system detected the existence of several photolysis products, and ion chromatography analysis of the photoproducts of OFL with a Metrohm 790 IC indicated the presence of fluoride, suggesting that fluorine atom was removed from the molecule of OFL. Dihydoxyl-ofloxacin (i.e. 8-Fluoro-3-hydroxy-9-(4-hydroxy-piperazin-1-yl)-6-oxo-2,3-dihydro-6H-1-oxa-3a-aza-phenalene-5-carboxylic acid), and hydroxyl-ofloxacin (i.e. 8-Fluoro-3-hydroxy-9-(4-methyl-piperazin-1-yl)-6-oxo-2,3-dihydro-6H-1-oxa-3a-aza-phenalene-5-carboxylic acid), defluoro-ofloxacin, demethyl-ofloxacin were suggested as the possible photolysis products and the analogues of the original antibiotic. Computations of the proton and carbon-13 NMR (nuclear magnetic resonance) chemical shifts (termed as NMR indices) of the possible photolysis products of OFL revealed the persistent molecular structure typical of quinolone, and the significance of such feature is discussed in terms of bacteria quinolone-resistance and nucleotide sequences of DNA gyrases in the clinical isolates publicized in scientific journals. It is postulated that sub-lethal exposures to the analogues helped bacteria develop resistance to original compounds. The NMR index of a given compound was proposed as a convenient parameter for estimation of antibiotic resistance.

Antibiotic residues in the polish coastal zone (southern Baltic Sea) - conclusions from 5 years study

K. Pazdro, Institute of Oceanology, Polish Academy of Sciences / Department of Marine Chemistry and Biochemistry; g. siedlewicz, Institute of Oceanology Polish Academy of Sciences / Marine Chemistry and Biochemistry Department; E. Kotlarska, Institute of Oceanology Polish Academy of Sciences / Marine Genetics and Biotechnology Department; M. Borecka, A. Białk-Bielińska, University of Gdansk / Department of Environmental Analysis Faculty of Chemistry; P. Stepnowski, University of Gdansk / Department of Environmental Analysis

In the course of last decade pharmaceuticals have been recognized as relevant environmental contaminants. Special attention should be paid to antibiotic residues. These bioactive compounds are detected in low concentrations but their continuous input to the environment and prolonged exposure may strongly affect bacterial populations and induce biological effects in nontarget organisms, potentially disrupting ecosystem processes. Seas can be seen as the final sink of the most persistent antibiotic residues. This is particularly true for the Baltic Sea, due to its natural features and particularly large catchment area. In this 5 years study (2010-2014) the occurrence of 14 pharmaceuticals from sulfonamides, quinolones and tetracyclines groups was evaluated. Sediment and water samples were taken during r/v "Oceania" cruises from the southern Baltic Sea along the polish coast. The procedures for the analysis of target compounds applied solid-liquid extraction and tandem SPE technique for isolation, enrichment and clean-up and liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) with electrospray ionization for final quantitative and qualitative analysis. 14 compounds were identified in samples at concentration levels of ng?g-1 d.w. (sediment) and ng L^{-1}(water). The occurrence frequency differed significantly among the compounds and matrices. The most frequent compounds were sulfamethoxazole, oxytetracycline, trimethoprim and sulfachloropirydazine for sediment samples and trimethoprim, sulfamethoxazole and enrofloxacin for seawater samples.These compounds revealed also the highest concentrations in the collected samples. Occurrence of the identified antibiotics was characterized by high spatial and temporal variability. Laboratory studies to test the influence of antibiotics identified in the sediments on microbiological activity in the sediments were performed applying seven strains isolated from Baltic sediments. The results showed, that tested antibiotics, mainly tetracycline and mixtures of compounds, inhibited the growth of the bacteria. The results of chemical analyses indicate contamination of coastal zone by antibiotic residues and the results of biological tests indicate that these contaminants may affect sedimentary microbial community. Consequently, the studies should be continued to establish more extensive chemical and ecotoxicological databases on antibiotics and their degradation products in the Baltic Sea area.

PharmCycle: Sustainable Pharmaceuticals

C. Floeter, HAW Hamburg / Department of Environmental Engineering; J. Andrä, Hamburg University of Applied Sciences (HAW Hamburg) / Department of Biotechnology; F. Beyer, Hamburg University of Applied Sciences (HAW Hamburg) / Department of Process Engineering; G. Cornelissen, J. Demmer, Hamburg University of Applied Sciences (HAW Hamburg) / Department of Biotechnology; J. Einfeldt, J. Heseding, Hamburg University of Applied Sciences (HAW Hamburg) / Environmental Engineering; K. Kuemmerer, Leuphana University Lüneburg / Institute of Sustainable and Environmental Chemistry

The key objective of the research project „PharmCycle" is to reduce prospective impacts of pharmaceuticals to the aquatic environment and drinking water supply. PharmCycle addresses therefore the life cycle of human pharmaceuticals, from the sustainable design and production, enhanced ecotoxicological risk assessment and improved wastewater treatment. The first cycle runs with antibiotics, which are selected from different prioritization lists due to their environmental concern. For these antibiotics an ecotoxicological risk assessment, integrating different chronic bacteria tests, is performed. A set of wastewater treatment pilot studies aims to reduce the concentration of the selected antibiotics in effluents. The second cycle runs with sustainable antibiotics, including newly designed antibiotic peptides, produced within PharmCycle using molecular and biotechnological methods. The third cycle runs with sustainable antibiotics designed with physical-chemical and in silico methods. Every cycle includes the upgraded ecotoxicologial risk assessment and investigations on wastewater treatment procedures. The approach of the project and first results are shown.

Pushing nanoparticle studies to the limit - working at environmentally relevant concentrations and with complex matrices (P)

WE099

Transport and toxicity for bacterial communities of reactive iron nanoparticles used for nanoremediation

M. Crampon, Bureau de recherches géologiques et minières (BRGM); j. hellal, P. Ollivier, C. Mouvet, BRGM

Highly toxic contaminants (e.g. As, chlorinated hydrocarbons, aso…) persist in the environment because of their low volatilization and/or hydrolysis and/or biodegradation. This situation is critical for public health and raises industrial and economic issues. Remediation techniques for these contaminants in groundwater are often technologically impossible, extremely expensive or hardly effective. Nanoparticles (e.g nZVI (Zero-Valent Iron), iron oxides, ferrate) applicable as in-situ reduction or oxidation agents for groundwater treatment show an extremely high reactivity leading to effective transformation of many contaminants into less toxic or benign products. However, these nanoparticles (NP) may also represent an additional contamination. Moreover, the different processes controlling the fate of NP and their toxicity towards microbial communities remain poorly understood. This study, part of the EU-project NanoRem (Taking Nanotechnological Remediation Processes from Lab Scale to End User Applications for the Restoration of a Clean Environment; EU FP7/2013-2017), aims to (i) study the mobility of NP in the presence or absence of biofilm by columns transport assays mimicking real aquifer conditions and (ii) to evaluate NP toxicity on bacterial communities (planktonic and biofilm grown onto sand). Results show that the mobility of nZVI widely depended on the water flow and/or NP concentration. The recovery at the column outlet was 1% for a 100 $m.d^{-1}$ and 40 % for 10 $m.d^{-1}$ water flow. The presence of biofilm in the column decreased its total porosity from 35% to 25%. Though the recoveries of nZVI in the presence or absence of biofilm were similar, the analysis of the sand showed that the variation of labile Fe content is concomitant with that of TOC, strongly suggesting NP-biofilm interactions. That was confirmed by CryoSEM images. Otherwise, measures of the denitrifying activity showed a toxicity of NP on planktonic bacteria starting at 50 mg $Fe.L^{-1}$ while cellular viability evaluated by Live and Dead method highlighted toxicity starting at 10 mg $Fe.L^{-1}$. It appears therefore that reactive NP, very useful for *in situ* groundwater treatment, can represent a source of emerging contamination. Other studies about mobility and toxicity of such particles will have to be conducted before a prospective large-scale application.

WE100

Nanoparticles, a risk for the environment through their transfer along an aquatic food chain?

F. Perrier, university of Bordeaux/ CNRS; M. Baudrimont, UMR CNRS EPOC Universite Bordeaux; S. Mornet, ICMCB; F. Pierron, Université de Bordeaux CNRS; N. Mesmer-Dudons, R. Maury-Brachet, University of Bordeaux CNRS; O. Simon, IRSN; A. Feurtet-Mazel, University of Bordeaux CNRS

Despite the significant arise of nanomaterials application, the lack of knowledge about their toxicity can be detrimental for the ecosystem sustainability. Trophic transfer is often referred as an important pathway of nanoparticles contamination in aquatic ecosystems being reportedly the main exposure route to organisms. Among their great variety of nature and characteristics, gold nanoparticles (AuNPs, PEG coating, diameter 10nm) have been chosen as model contaminant due to their high stability in solution. This work aims to characterize AuNPs transfer, sequentially performed in controlled conditions, within three food chain levels. Thereby natural river biofilms contaminated in laboratory for 48h at low AuNPs' concentrations (of 10 and 100-fold lower than its LD_{50} for diatoms) were grazed by the fish *Hypostomus plecostomus* during a 21-days laboratory experiment. Analyses revealed that biofilms presented a high AuNPs retention capacity. Secondly, results point out that AuNPs were effectively transferred from natural biofilms to the grazer fish showing their ability to enter the food chain. Regarding AuNP fish distribution, organs involved in metabolism and excretion (liver and kidney) presented a significant bioaccumulation. Interestingly, AuNPs clearly penetrated the brain at the highest exposure concentration. Moreover, electronic microscopic observations showed tissue alterations indicating inflammatory responses. Following the concentrations used in the previous exposure essay, in a second phase, the predator *Anguilla anguilla* was fed with AuNP-spiked fish meat during a 21-days period. In reference to previous results, a transcriptomic approach was then focused in liver and brain tissues to evaluate the impacts on metabolic pathways.

WE101

Fate of TiO2 nanoparticles in the aquatic environment in the presence of anthropogenic compounds

S. Ilina, N. Baran, N. Devau, BRGM; D. Slomberg, Labex Serenade/CEREGE/Aix-Marseille Université; N. Sani-Kast, ETH Zurich / Institute for Chemical and Bioengineering; J. Labille, CNRS; M. Scheringer, ETH Zurich / Institute for Chemical and Bioengineering; P. Ollivier, BRGM

The increasing production and use of nanoparticles (NP) in consumer products inevitably lead to ENP emissions into the environment. The physicochemical properties of NP depend on various parameters (e.g. pH, cations, IS). In natural waters, the stability of NP can vary as a function of a sum of these parameters and occurs by one of the numerous scenarii. In particular, the presence of anthropogenic organic molecules (AOM) can change the NP fate. Also, the presence of NP may affect the organic pollutants (fate and toxicity). The main objective of the work was to study the aggregation of TiO_2 NP (pure hydrophilic 100 % rutile and pure hydrophilic 100 % anatase, 5−30 nm) in the presence of the most frequently occur and representative pesticides (glyphosate, AMPA, 2.4D) in natural waters considering lab experiments under relevant aqueous conditions (pH, ionic strength, presence and concentrations of mono- and bivalent cations). The presence of pesticides affected TiO_2 NP homoaggregation in solutions (IS=10^{-3}M - 10^{-2}M) with pH values below the NP point of zero charge (PZC) for the anatase NPs (pH=6.5) and with pH values above the NP PZC for the rutile NPs (pH=4.5). No changes in NP aggregation were observed in very low (IS=10^{-4}M) or very high (IS= 10^{-1}M) ionic strength solutions. The presence of the pesticides caused a significant modification of the NP surface charge (zeta potential) over a large range of salt concentrations (IS=10^{-4}M - 10^{-1}M). Compared to mono-valent cations (Na^+), bi-valent cations (Ca^{2+}) favor an increase in zeta potential of NP (anatase and rutile) at pH 8. There is no significant difference between at pH 5. Finally, these results demonstrated that, among the studied AOMs, glyphosate (with 4 pKa-s from 0.8 to 11) affects NP aggregation/stabilization in a wider range of physicochemical conditions. Overall, these results will aid in the evaluation of potential environmental risks posed by engineered NPs in the aquatic environments exposed to pesticide load.

WE102

Quantification of ionic silvers released from different surface-coated silver nanoparticles in the presence of fulvic acids

Y. Jung, KIST-Europe; Y. Kim, S. Baik, KIST Europe / Environmental Safety Group

Studying the roles of natural organic matter (NOM) in fate and transport of nanoparticles (NPs) after their releasing into the aquatic environment has been performed by many other researchers. Silver nanoparticles (AgNPs) were chosen for this study due to their potential toxic effects from both ionized and nanoparticulated forms. Especially, previous researches suggested that the toxic effects of AgNPs are mainly attributed to the silver ions (Ag^+) released from AgNPs. The objective of this study, therefore, is to assess the roles of NOM in dissolution for two AgNPs, differently coated with citrate (Cit) and branched polyethylenimine (BPEI). Pony Lake Fulvic Acid (PLFA) was selected as a model NOM due to its higher contents of S and N with high affinity to metallic Ag and Ag^+, compared to the other commercially available NOM standards. PLFA solutions were prepared in 10 mM $NaNO_3$ with the concentrations of 5 and 30 mg/L. Time-dependent dissolution of AgNPs was then monitored in the absence and presence of PLFA for 2 days and 6 days, respectively. Quantification of Ag^+ released from AgNPs for both cases was achieved by using an inductively coupled plasma mass spectrometer (ICP-MS). Prior to the analysis by ICP-MS, Ag^+ ions were separated from AgNPs particles using a ultrafiltration filter with 10 kD of molecular weight cutoff (MWCO) and a dialysis membrane with 0.5~1 kD of MWCO in the absence and presence of PLFA, respectively. As comparing to the case without fulvic acids (FA), significant decreasing of Ag^+ released from Cit-AgNPs was occurred in the presence of FA. This result may be from stronger interaction of Ag^+ with S and N of FA or shielding the active sites of NPs by FA. In contrast, Ag^+ released from BPEI-AgNPs was slightly increased in the presence of FA. Concentration of FA also played an important role in dissolution of AgNPs. For Cit-AgNPs, the amount of Ag^+ released in 5 mg/L of PLFA was 12.1 ± 2.16 μg/L, while the amount of Ag^+ released in 30 mg/L of PLFA was significant lower as showing of 2.62 ± 0.44 μg/L. The amount of Ag^+ released from BPEI-AgNPs in 30 mg/L of PLFA, 1.08 ± 0.19 μg/L, was also slightly lower than that in 5 mg/L of PLFA, 1.90 ± 0.02 μg/L. These lower releases of Ag^+ in higher concentration of FA indicate that higher FA may enhance the interaction of Ag^+ released from AgNPs with FA. Our dissolution research suggests that FA in the environment may reduce free Ag^+ and toxic effects of AgNPs to aquatic organisms.

WE103

Interference of signal transduction in zebrafish (Danio rerio) to zinc oxide nanoparticles

W. Kim, Korea Institute of Toxicology (KIT) / Environmental Toxicology Research; J. Choi, Korea Institute of Korea KIT

Zinc oxide nanoparticles (ZnO NPs) are being utilized in an increasing number of fields and specialties (commercial applications). While the general toxicity or oxidative stress has been extensively studied, it is still unknown what toxicological pathway may occur following developmental stage. In this study, the developmental toxicity of ZnO NPs were investigated in the embryo-larval zebrafish, the transcriptional expression profiles by ZnO NPs was also investigated to ascertain novel genomic responses related to specific toxicity pathway. Zebrafish embryos were exposed to 0.01, 0.1, 1, and 10 mg/L ZnO NPs for 96 h post-fertilization (hpf). The ZnO NPs was found to exert a dose-dependent toxicity to zebrafish embryos and larvae, reducing the hatching rate and inducing malformation such as pericardial edema, yolk sac edema, and physical deformities. As the results of gene expression profiling using microarrays, total 1,586 genes were differentially up– or down–regulated (fold change > 2) in zebrafish followed by the exposure of ZnO NPs and $ZnSO_4$ (498 and 191 in ZnO NPs, and 681 and 216 $ZnSO_4$, respectively). Several genes that differentially regulated in ZnO NPs exposure shared similar biological pathways with those observed in $ZnSO_4$ exposure, but six genes (*aicda, cyb5d1, edar, intl2, ogfrl2* and *tnfsf13b*) were differentially regulated in ZnO NPs exposure, opposite or not in $ZnSO_4$ exposure. Real-time RT-PCR confirmed that the genes exposed ZnO NPs exposure was significantly changed comparing with the $ZnSO_4$ exposure. Our results are helpful to understand the mechanisms of ZnO NPs induced developmental toxicity in zebrafish.

WE104

Detection of metal-based nanoparticles in the river Dommel in the Netherlands

A. Markus, DELTARES / DSC; P. Krystek, Institute for Environmental Studies IVM VU University Amsterdam; J. Parsons, University of Amsterdam / IBED; P. Tromp, TNO; P. de Voogt, University of Amsterdam / IBED; E. Roex, DELTARES; R. Laane, University of Amsterdam IBED Institute

We investigated the occurrence of inorganic nanoparticles in a natural\nsystem, the river Dommel in the Netherlands. The river itself is\nwell-studied as far as hydrology and water quality is concerned, easily\naccessible and one major wastewater treatment plant discharges onto\nthis river. We sampled the river water at various locations along the\nriver and collected samples of influent, effluent and sewage sludge\nfrom the treatment plant. The sampling campaign was carried in June\n2015 and these samples were analysed for seven metals (Ag, Au, Ce,\nLa, Ti, Zn and Zr) using inductively coupled plasma mass-spectrometry\n(ICP-MS), ultrafiltration and scanning electron microscopy (SEM).\n\nFrom the results we conclude that there are indeed nanoparticles\npresent in the system we studied, as we found titanium and gold\nparticles in the influent and effluent. The river water also contains\nnanoparticles, although they occur in clusters or attached to natural\ncolloids, so that the effective size is above 0.4 um. At most\n10 to 20% of the mass concentration is made up of free particles with\na size smaller than 20 nm or dissolved elements.\n\nWe found evidence that there is no appreciable anthropogenic emission\nof cerium into the river, based on the geochemical relationship\nbetween cerium and lanthanum. Besides, the effluent of the treatment\nplant has lower concentrations of the examined metals than the\nsurface water upstream. The treatment plant discharges much less of\nthese metals than estimated using previous publications. However, a\npotential source of titanium dioxide nanoparticles is their use\nin coatings of exterior surfaces, as the concentration of titanium\nincreased considerably in the urbanised area of the river Dommel.

WE105

Engineered nanoparticles in cosmetics according to EU 2011/696/EU: sample preparation and analysis

M. Velimirovic, Department for Environmental Geosciences; S. Wagner, Helmholtz Centre for Environmental Research GmbH - UFZ / Department of Environmental Geoscience; F. Abdolahpur Monikh, University of Vienna / Department for Environmental Geosciences; F. Von der Kammer, Vienna University / Department of Environmental Geosciences; T. Hofmann, University of Vienna / Department of Environmental Geosciences

The applicability of a previously developed generic scheme for detection, characterization, and quantification of engineered nanoparticles (ENPs) in a complex matrix has been extended to real product samples containing unknown particles. The extended generic multi-step sample preparation procedure includes: 0) pre-characterization of the sample, I) homogenization of the sample, II) ENP separation from the matrix, III) ENP enrichment, and IV) ENP stabilization. In this study, sunscreen, as a common example of complex matrix, which potentially contains TiO_2 as UV-filter was selected to apply the proposed extension of generic sample preparation approach. Pre-characterization in order to identify possibly present ENPs was designed and applied to the sunscreen sample. We demonstrated that the extended generic sample preparation scheme is valid and pre-characterization of the sample is a useful tool to isolate target ENPs for further analysis. TiO_2 ENPs present in the sunscreen could be isolated by a combination of ultra-centrifugation and hexane washing with sufficiently high recoveries for performing further analysis on the particle size. To apply EU 2011/696/EU recommendation where materials are classified as nanomaterials based on number-based particle size distributions, the size distribution of the isolated TiO_2 ENPs was determined by asymmetric flow field-flow fractionation (AF^4) coupled to multi-angle laser light scattering (MALLS) and inductively-coupled plasma mass spectrometry (ICP-MS). AF[4]-MALLS-ICPMS analysis indicated only a slight shift of the size distribution towards larger diameters. Therefore the mass-based size distribution, which was derived from AF[4]-ICPMS analysis, was converted into a number based size distribution. The applied conversion algorithms are very sensitive towards mass-based signals of small particle sizes. Consequentially high signal noise levels for small particles potentially introduce large errors in the number-based ENP size distribution. *Acknowledgment* – The NanoDefine project has received funding from the European Union's Seventh Programme for Research, Technological Development and Demonstration under grant agreement No 604347-2.

Pitfalls and challenges of microplastic analysis with Raman micro-spectroscopy

F.R. Storck, DVGW-Technologiezentrum Wasser / Analysis and Water Quality; M. Pittroff, O. Happel, H. Brauch, DVGW-Technologiezentrum Wasser

Microplastic residues both in marine and freshwater systems have recently been a topic discussed in the public and in the scientific community. For freshwater systems, available information is still scarce. An increasing number of studies reports toxicological and ecotoxicological effects of microplastics. Particles with a diameter < 300 μm are supposed to be very important and interesting for toxicological and ecotoxicological effects. A major problem is the lack of standardised methods for sampling and analysis of microplastics. Many studies so far published relied even on the naked eye to identify particles as polymers instead of chemical identification. Toxicological effects may be related to particle size, shape, material and particle concentration. A very promising approach to detect very small particles and to achieve the latter information is the use of Raman micro-spectroscopy which provides a high spatial resolution of 1 μm. First, the focus was put on aqueous matrices and the extraction and detection procedure. An example of recently not investigated sources for microplastic particles could be slow or controlled-release fertilizers coated with polymer resins and super absorbers, both used in forestry, agricultural and horticultural applications. The latter could be transferred to surface waters or groundwater. Due to the novelty of the subject, this study provides some information on potential pitfalls and challenges of microplastic analysis.

Ecological traps for wildlife driven by pollutants (P)

WE107

Heavy metals, oxidative stress and immune function in common moorhens from natural and artificial wetlands

J. López Perea, Instituto de Investigacion en Recursos Cinegeticos / Unidad de Ecología y Ciencia Animal; N. Vallverdu-Coll, IREC / Wildlife Toxicology; R.R. Martin-Doimeadios, University of Castilla La Mancha / Analytical Chemistry and Food Technology; M. Jiménez-Moreno, University of Castilla-La Mancha / Department of Analytical Chemistry and Food Technology; R. Mateo, U.C.L.M.-C.S.I.C. / Instituto de Investigacion en Recursos Cinegeticos

The use of effluent from wastewater treatment plants for maintenance of wetlands is becoming common practice in semiarid regions. We suggest that this type of ecosystem could act as an ecological trap, because it concentrates pathogenic organisms and chemical pollutants coming from several sources. Heavy metals have been reported as a cause of lethal poisoning and sublethal effects by impairing biochemical processes. This study determined levels of heavy metal in waterbirds from a wetland that receive effluent from a wastewater treatment plant (Navaseca Lake) and how these pollutants alter oxidative stress biomarkers and the immune function in comparison to birds from non-polluted sites (Tablas de Daimiel National Park, TDNP) in Central Spain. Blood samples were collected from 127 common moorhens (*Gallinula chloropus*) to determine levels of As, Cd, Mn, Hg, Pb, Se, Cu and Zn, oxidative stress biomarkers and immune function parameters. Mn, Hg and Se were significantly higher in moorhens from TDNP. These recent findings are in contrast to our previous work at these sites in which we found higher PCB levels in birds from Navaseca Lake. Moorhens from TDNP displayed higher levels of retinol, α-tocopherol, MDA and SOD activity. Moorhens from Navaseca showed higher bactericidal activity in blood and higher haptoglobin levels in plasma and slightly lower cellular response to phytohaemagglutinin injection. Hg and Se levels were positively correlated ($r=0.410$, $p< 0.001$). Hg and Se were positively correlated with SOD activity and negatively correlated with GPX and bactericidal activity. Moorhens from Navaseca Lake have shown higher levels of some POPs, but lower levels of heavy metals compared with birds from TDNP. Additionally, evidence of increased oxidative stress and capacity to cope with pathogens, as shown by the elevated bactericidal activity and haptoglobin levels was found. These results may indicate that moorhens from Navaseca Lake are at greater risk of exposure to some organic pollutants and a wider range of pathogenic bacteria than at TDNP. This could explain the overexpressed immune response and the evidences of oxidative stress. That the highest levels of heavy metals were found in moorhens from TDNP may show the highest accumulation of these pollutants in this floodplain. Navaseca Lake, as a eutrophic wetland, attracts high numbers of waterbirds as feeding area, but it may act as an ecological trap due to biotic and abiotic threats to birds.

WE108

Does food quality and quantity, limited by parental feeding strategies, influence offspring fitness? A case study in Lesser black-backed gulls (Larus fuscus)

C.S. Santos, Ghent University (UGent) / Terrestrial Ecology Unit TEREC Department of Biology; A. Sotillo, Ghent University / Terrestrial Ecology Unit TEREC Department of Biology; M.S. Monteiro, Aveiro University / Department of Biology and CESAM; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; S. Loureiro, Universidade de Aveiro / Biology; L. De Neve, L. Lens, Ghent University / Terrestrial Ecology Unit Biology Department

Exposure of free-ranging bird populations to varying environmental conditions (e.g. contamination and food availability) are factors with potential to modify individual fitness at different developmental stages by triggering changes in normal physiological processes (e.g. enzymatic functions). The Lesser Black-backed Gull (*Larus fuscus*) is a seabird species with a high individual variation in foraging strategies and an ability to thrive in urban landscapes. Over the last decades, these gull species foraging habits have become increasingly dependent on human activities – and food resources- which in return increases susceptibility of exposure to toxic substances. The ingestion of contaminated food may be then transferred from adult birds to their offspring via parental care during chick rearing. The goal of this study was to address how a shift in foraging behaviour of *L. fuscus* adults, during chick development, and coupled with food quantity provided may interact with chick fitness during breeding. In order to assess this topic, during 2016 breeding season, *L. fuscus* eggs were collected in Oostende harbour (first or second egg collected). Eggs were only collected at sites where the natural hatching and survival rates are known to be very low, and were then moved to specifically designed aviaries (VOC Oostende). There eggs were bred in RCOM 20 SURO incubators and chicks hand-raised for 30 days. After hatching, individuals were randomly assigned to 3 different diet treatments: a predominantly marine (80% marine: 20% terrestrial), predominantly terrestrial (80% terrestrial: 20% marine) or mixed (50% marine: 50% terrestrial) diet, and food was provided ad libitum. In addition, two other additional diets were tested in which daily energetic input was reduced to comply with minimum energetic requirements: marine restricted or terrestrial restricted. Following this, chicks' were measured every 2-3 days and blood samples collected (days 12, 21 and 30) for posterior assessment of mercury burden, lipid peroxidation and activity of a battery of enzymatic markers (cholinesterase, lactate dehydrogenase, catalase and glutathione-*S*-transferase). Mercury burdens was typically higher in chicks fed a predominantly marine diet. Furthermore, differences in enzymatic activities were observed in chicks between diets and varying with age, corroborating that both quality and quantity of food provided may interact with early chick fitness.

WE109

Persistent organic pollutants (POPs) in Pontoporia blainvillei from Franciscana Management Area II - Southeastern coast of Brazil: assessment of population structure and temporal trend

R.C. Montone, Instituto Oceanografico - Universidade de Sao Paulo / Departamento e Oceanografia Fisica Quimica e Geologica; P. Mendez Fernandez, IOUSP / Department of physic oceanography; S. Taniguchi, University of São Paulo / Physical Oceanography department; M. Alonso, Biophysics Institute, Federal University of Rio de Janeiro, Brazil / Radioisotopes lab; R.M. Gonçalves, UNESP - UNIV ESTADUAL PAULISTA; A.M. Barbosa, University of São Paulo - Oceanographic Institute / Departament of Oceanography Physical chemical and geological; M.C. Santos, University of São Paulo / Biology oceanography department

Persistent organic pollutants (POPs), such as polychlorinated biphenyls (PCBs) and dichlorodiphenyltrichloroethane (DDTs), are synthetic compounds that bioaccumulate in fat tissues and biomagnify through the food web due to their physicochemical properties. Marine mammals have been proposed as sentinels of marine environmental health, since these organisms are top predators and may accumulate high concentrations of organic pollutants. Franciscana dolphin (*Pontoporia blainvillei*) is a small cetacean found exclusively in the Southwest Atlantic Ocean and is the most endangered dolphin in the area. Recently the four Franciscana Management Areas (FMAs I to IV), initially proposed to improve the management of the species, were revised. In order to contribute to these FMAs, persistent organic pollutants were analyzed in 101 blubber samples of *Pontoporia blainvillei* collected in the FMA II corresponding to the coast of the state of São Paulo (São Paulo North, SPN, São Paulo Center, SPC, and São Paulo South, SPS). POPs distribution were similar among the three Franciscana stocks with a predominance of PCBs (286 – 22,823 ng g^{-1} lipid weight, lw) and DDTs (39 – 7,186 ng g^{-1} lw). The population from FMA II - SPC presented the highest values. This was expected since in this area a major industrial complex and the largest harbor in South America are located. The three Franciscana stocks showed similar profiles of PCB congeners, with predominance of hexa-chlorinated compounds (mainly PCB-153 and PCB-138), representing approximately 48% of the total PCB amount. Significant differences were observed between juveniles and adults, while among sex there is no significant difference except for DDTs, which were detected in relatively higher concentrations in males. The PCB/DDT ratio showed similarity between SPN and SPC populations; however they were significantly different from SPS ($p < 0.05$). Assessment of PCB and DDT in Franciscana dolphins from FMA II in the last 15 years (2000 – 2014) suggests a slight decline in their concentrations. POPs data support the subdivision of FMAII, especially the southern area (i.e. SPS) that could be considered as a different Management Unit for future conservation plans on the species.

Fish model species in environmental toxicology (P)

WE110

Cross-species extrapolation of uptake and disposition of neutral organic chemicals in fish using a multi-species physiologically based toxicokinetic model

M. Brinkmann, RWTH Aachen University, Institute for Environmenta / Department of Ecosystem Analysis; C. Schlechtriem, Fraunhofer IME / Bioaccumulation and Animal Metabolism; M. Reininghaus, K. Eichbaum, RWTH Aachen University, Institute for Environmental Research / Department of Ecosystem Analysis; S. Buchinger, Federal Institute of Hydrology / Department G Biochemistry Ecotoxicology; G. Reifferscheid, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis; T. Preuss, Bayer CropScience / Environmental Modelling

The potential to bioaccumulate is generally considered an unwanted substance property. Consequently, chemical legislations, such as the European REACH regulation, require the chemical industry to provide bioconcentration data for chemicals that are produced or imported at volumes exceeding 100 tons *per annuum,* or if there is concern that a substance is persistent, bioaccumulative and toxic. To fill the existing data gap for chemicals below this stipulated volume without the need for additional animal experiments, physiologically based toxicokinetic (PBTK) models can be used to kinetically predict whole-body bioconcentration as well as internal concentrations of neutral organic chemicals in different fish tissues. PBTK models have been developed for many different fish species with promising results. In this study, we developed PBTK models for zebrafish (*Danio rerio*) and roach (*Rutilus rutilus*) and combined them with existing models for rainbow trout (*Onchorhynchus mykiss*), lake trout (*Salvelinus namaycush*) and fathead minnow (*Pimephales promelas*). The resulting multi-species model allows for cross-species extrapolation of the bioaccumulation potential of neutral organic compounds. Predictions were compared with experimental data and were accurate for most substances. Our model holds strong potential for the probabilistic risk assessment of a chemical's bioaccumulation potential with special emphasis on cross-species extrapolation of sensitivity.

WE111

Fish Metabolism Studies

G. Gonsior,

Stagnating growth in global food production is leading to an increased focus on alternative food resources. The global aquaculture industry continues to expand since fisheries have to deal with decreases in fish stocks and climatic effects. Fresh water fish farming is one of the most productive sectors for this industry. This leads to the problem: How to feed the fish? High quality food might be needed as a resource for humans. Therefore the risk is high that pesticide contaminated food will be fed to animals like fish. In most cases these residues will be metabolised. Therefore it is essential to identify metabolites which have a potential risk for human health. So far no specific guideline for fish metabolism is available. A testing approach will be presented with the focus on lab testing.

WE112

Investigations on biodiversity and ecosystem health of the river Nidda within the framework of the project 'NiddaMan'

A. Dieterich, University of Tubingen / Animal Physiological Ecology; M. Schweizer, R. Triebskorn, University of Tuebingen / Animal Physiological Ecology; H.-. Köhler, University of Tuebingen / Institute of Evolution and Ecology Animal Physiological Ecology

With almost 100 km length and a catchment of 2000 km², the river Nidda represents a great number of European streams. Being in its natural state near the spring in the Vogelsberg Mountains in Upper Hesse (Germany), the river Nidda rapidly changes its chemical and biological water status due to anthropogenic influences along its course. Discharges of local wastewater treatment plants, diffuse emissions of agricultural substances and substance inputs from tributaries as well as structural alterations are affecting the river on its way downstream, until entering the river Main near Frankfurt (Germany). The 'biodiversity and ecosystem health part' of the BMBF-project 'NiddaMan' investigates the ecological importance of diverse stress factors affecting fish in the Nidda catchment area. In an active monitoring approach, rainbow trout (*Oncorhynchus mykiss*) are directly exposed in cages to the water of the Nidda. Furthermore, feral fish are investigated at different sites in the catchment area with the aim to validate these responses obtained by active monitoring .To identify the influence of different input sources, like wastewater treatment plants, a local mineral spa and a papermill, samples from representative sites are also chemically analysed , and in addition, biotests addressing genotoxic- (micronucleus assay), cytotoxic- (histopathology), embryotoxic- (DarT) and dioxin-like (EROD assay) effects are conducted. The overall aims of this project part are the development of strategies to counteract water quality impairment induced by environmental stressors and to support river ecosystem recovery. Acknowledgement: The project NiddaMan is funded by the Federal Ministry for Education and Research (BMBF) within the ReWaM initiative under project code 02WRM1367.

Pollution induced effects in feral fish from the river Holtemme assessed by toxicogenomic techniques

N. Markert, RWTH Aachen University / Ecosystem Analysis ESA; B. Deutschmann, RWTH Aachen University / Institute for Environmental Research Biology V; S. Tang, School of Environment and Sustainability; S. Beitel, University of Saskatchewan - Toxicology Centre / Toxicology Centre; F. Yang, Helmholtz Centre for Environmental Research UFZ; M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; B. Thalmann, RWTH Aachen University, Institute for Environmental Research / Bio ESA; T. Seiler, RWTH Aachen University / Ecosystem Analysis; W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis; M. Hecker, University of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis

Anthropogenic and natural pollutants often result in adverse effects on different levels of biological organization. The aim of this project was the linkage of biochemical and physiological responses with parameters of demographic relevance (survival, growth, reproduction) by the use of toxicogenomic techniques. Deep sequencing technologies of the whole transcriptome enables the investigation of the specific mechanisms by which stressors such as xenobiotics can interact with molecular toxicity pathways. Therefore, a wide range of potential impacts of complex chemical mixtures can be examined. In this study, samples of wild brown trout (*Salmo trutta)* from the river Holtemme (Germany) were collected in a sampling campaign by the RWTH Aachen University and Helmholtz Centre for Environmental Research (UFZ) in 2014. This river is of particular scientific interest due to its specific point sources of pollution. Therefore, four sampling sites were chosen to determine effects of agricultural use or discharges of waste water treatment plant (WWTP) effluents. Hepatic tissues of fish samples were used for RNA-sequencing-by-synthesis technologies in cooperation with the Toxicology Centre of the University of Saskatchewan (Canada). The first functional pathway analysis of the expression data shows more than 600 significantly altered genes at study sites downstream of WWTP effluents and agriculturally used area, respectively. Earlier studies detected pollution induced/inhibited effects on micronucleus formation, biotransformation enzyme activity, biomarker of exposure and oxidative stress in the same fish samples from the river Holtemme. This reveals that multiple known toxicity pathways have been altered, including changes of phase I metabolism enzymes expression or steroid biosynthesis. Further analysis should investigate pollution effects and specific mechanisms of actions with the ultimate goal to predict potential adverse outcomes as part of the environmental risk assessment of chemicals and to discover new biomarkers for ecotoxicological application.

WE114

Biomarkers measured in situ using native fish in three agricultural areas associated with environmentally valuable wetlands in Costa Rica

F. Mena, Universidad Nacional / Instituto Regional de Estudios en Sustancias Toxicas; E. de la Cruz, Universidad Nacional / IRET; M. Fournier, IRET, UNA / Central American Institute for Studies on Toxic Substances IRET; C. Ruepert, Universidad Nacional / IRET; L. Castillo, Universidad Nacional, Costa Rica / IRET

Indigenous fish have been used to apply a biomarker approach in environmental evaluations in Costa Rica,. Caging experiments using the species *Parachromis dovii* have been carried out along environments exposed to different agricultural activities. *In situ* 48-hour exposures of caged *P. dovii* were performed at three different areas of the country, characterized by agricultural crops associated with wetlands: one at the North-Pacific, close to the Palo Verde lagoon (Palo Verde National Park) four sites where studied in this area where mainly rice and sugarcane are grown. A second area is located at the North zone, upstream of the Refugio de Vida Silvestre Caño Negro (RAMSAR) four sites were sampled there, where the main crop is pineapple. The third zone is on the Caribbean side of the country, six sites were sampled on a region characterized by banana, rice and pineapple plantations, upstream from an estuarine lagoon (Laguna Madre de Dios). A set of biomarkers: cholinesterase (ChE), glutathione S-transferase (GST) and catalase (CAT) activities; as well as lipid peroxidation (LPO) were measured in fish exposed *in situ*. Pesticide residue analyses were performed for every fish deployment experiment and relationship between pesticide pollution and biomarker responses was evaluated. Pesticides were present in all three studied areas. In Caño Negro, residues were only detected in one of the four sampled sites. The other two areas had different pesticide concentrations in all sampling sites. Biotransformation and oxidative stress-related biomarkers (GST, CAT and LPO) showed clear differences at one of the Palo Verde sites, where several pesticides were detected in water. ChE was inhibited at two Caño Negro sites but pesticides were only detected in one of them. In the Madre de Dios area, all four biomarkers

showed significant changes at different sites, agreeing with the presence of pesticides measured in water samples. Data suggest that biomarkers measured in caged *P. dovii* can give information on early effects caused by exposure to pesticides as significant changes were observed at most impacted sites. Regarding the areas and crops assessed, some differences in environmental conditions and agricultural practices might be enhancing runoff from agricultural areas in the Caribbean zone compared to the other two areas.

WE115

Effects of Long- term exposure of different intensities magnetic field on biochemical and enzymatic parameters in Acipenser ruthenus

A. Charmi, Khoramshahr university of marine science and technology / Department of Marine Biology Faculty of Marine Science; A. Movahedinia, Khoramshahr university of marine science and technology; M. Bahmani, International Sturgeon Research Institute; N. Salamat, Khoramshahr university of marine science and technology

Considerable attention is focused on the effects of electromagnetic field (EMF) due to its wide-ranging use in everyday life. Anthropogenic electromagnetic fields were induced to the aquatic environment by different sources such as underwater power and telecommunication cables, electrical heating cables for oil and gas pipelines as well as generating units and submerged substations. It is known that magnetic field can change cell behaviors and activation by affecting the biochemical and/or biophysical process in aquatic animals. In this study, the effects of variable magnetic fields on biochemical factors of Acipenser ruthenus were investigated. 14 juvenile fish was exposed to magnetic fields with different intensities (3, 5, 15, 25 mt) induced by electrical power supply for 2 months. The results showed that there was not significance difference in growth rate between the control and exposed fish. However, there were significant differences in lysozyme level and complement activity between control and exposed fishes.

WE116

Sublethal effects of copper in early life stages of development of rainbow trout (Oncorhynchus mykiss)

S.L. Weeks Santos; B. Morin, P. Gonzalez, University of Bordeaux; J. Cachot, EPOC- Université de Bordeaux

Copper (Cu) is an essential element needed in small quantities for organism metabolism as well as for functioning of some essential enzymes. Due to its fungicidal properties, it has been extensively used for vineyard treatment against plagues resulting in its high emission into soils and aquatic environments. At high concentrations, copper can inhibit growth and interfere in several cellular processes including respiration, synthesis of proteins and cellular division. The aim of this work was to study the possible sublethal effects that copper could cause in the early life-stages of development of rainbow trout fish (*Oncorhynchus mykiss*). Eyed-stage embryos rainbow trout (265 °J) were exposed in semi-static conditions to sublethal concentrations of $CuSO_4$ up to the larval stage (528 °J) under laboratory-controlled conditions. During 23 days, they were exposed to the environmentally-realistic concentration of 2 μg/L Cu^{2+} and to a 10 fold higherconcentration 20 μg/L Cu^{2+}. Several biological and morphological (survival, hatching success, malformation, growth), functional endpoints (swimming activity) and genotoxicity (DNA damage) were studied. Exposure to 20 μg/L Cu^{2+} resulted in a significant reduction in hatchability (63%) and an increase of half-hatched embryos (25%). Copper had an inhibitory effect on hatching. At the end of the exposure, no significant differences were observed in growth of the larvae exposed to the highest Cu concentration. However, larvae exposed to the weakest Cu concentration resulted with a major growth in comparison to the control. Malformations were recorded in larvae of 492 °J, and the percentage of malformed larvae was significantly higher for the conditions of 2 and 20 μg/L Cu^{2+} (with 53 and 60% of malformations respectively) in comparison to the control (27% of malformation). For both conditions, the skeletal malformations were the most observed. Behavioural study was conducted at the end of the experience by imaging analysis system Daniovision (version 10.0 of Noldus). Larvae exposed to the weakest copper concentration were less mobile, whereas no significant differences were observed in total distance travelled by the larvae exposed to the strongest concentration of copper. A comet assay was done and no evidence of significant DNA damage was observed for both conditions. This study confirms the toxic effects of copper on early life-stage of rainbow trout, even at the lowest environmentally relevant tested concentration.

WE117

Zinc or swim: are mechanisms of sub-lethal zinc toxicity conserved in a key southern hemisphere fish species?

N. McRae, University of Canterbury / School of Biological Sciences; S.K. Gaw, University of Canterbury / Chemistry; C.N. Glover, Athabasca University

Metal contaminants have been shown to cause sublethal toxicity in model fish species. However, very little is known regarding the sensitivity of "non-model" fish, particularly indigenous species in the Southern hemisphere. This study investigated the impacts of zinc, a ubiquitous metal contaminant, on the freshwater fish, inanga (*Galaxias maculatus*). Inanga is widespread throughout the Southern hemisphere, is a frequent inhabitant of near-coastal streams impacted by pollution, and is of significant cultural and economic importance. Inanga also have a number of unusual physiological characteristics, including extensive use of the skin as a transport surface, and an amphidromous life-history that conveys an exceptional ionoregulatory ability. These factors may alter the relationship between metal exposure, accumulation and impact, particularly for metals such as zinc, which have impacts on epithelial processes. To determine mechanisms of sublethal toxicity, fish were exposed to graded, environmentally-relevant concentrations of zinc over 96 h (1000, 270 10, 0 µg L^{-1}). Endpoints measured included those relating to ionoregulatory disturbance (whole body calcium and sodium influx), respiratory/metabolic impairment (respirometry) and oxidative stress (catalase activity and lipid peroxidation). Tissue accumulation of zinc was also measured. Results indicated that zinc exposure stimulated catalase activity, but also increased hepatic lipid peroxidation. Effects were also seen on ion transport, with an impairment of calcium influx, consistent with other studied fish, but a stimulation of sodium influx. However, these effects were only observed at the highest exposure concentration (1000 µg L^{-1}). No effects on metabolic rate were observed, and whole body zinc was homeostatically-regulated beyond the lowest zinc exposure level. Overall, these data suggest some similarities in terms of inanga response to zinc relative to model fish, but also some key differences (increase in sodium influx). These data were the first to examine the sensitivity of juvenile galaxiid fish to zinc, information that will be critical to ensuring adequate environmental protection of this important species.

WE118

Recovery of seahorse (Hippocampus reidi) after acute and subchronic exposure to water soluble fraction of diesel oil using a DNA damage approach

F. Cariello Delunardo, Applied Ichthyology Laboratory; L.C. Medeiros, A. Chippari Gomes, Universidade Vila velha / Applied Ichthyology Laboratory

The main goal of this study was to investigate the effects of acute (12, 24, 48 and 96h) and subchronic (168 and 360h) exposition to 50 % water soluble fraction (WSF) of diesel oil on the integrity and functionality of DNA in seahorse *Hippocampus reidi* (Ginsburg, 1933). In addition, we investigated the ability of fish to recover (504h without contamination) after 168h of exposure to the above WSF using the same DNA endpoints. The comet assay and the micronucleus test were used in peripheral blood erythrocytes of 112 specimens (16 fish per condition/time: 8 for WSF exposure and 8 for its respective control group; and 16 for recovery experiment: 8 for post-exposure period and 8 for it control group). Our results revealed significant increases in the frequencies of DNA strand breaks and micronuclei frequency with increasing exposure period and thus demonstrated the genotoxic and mutagenic potential of this contaminant on fish. Furthermore, both techniques detected the highest DNA damage at 168 h of exposure, followed by statistically decline at 360 h of exposure. During the recovery experiment, DNA strand breaks and micronuclei frequency were significantly reduced after 504h post-exposure, when compared with 168h exposure group. The results supported the integrated use of comet assay and micronuclei test in determining the early impact and recovery from acute and subchronic exposure caused by diesel oil contamination. Besides, *H. reidi* proved to be a useful bioindicator in the determination of diesel spill impact on fish populations. Financial support: FAPES, UVV.

WE119

Effects of four substituted phenylamine anti-oxidants (SPAs) in chronic fathead minnow early life stage tests

J. Parrott, Environment Canada / Water Science and Technology Directorate; R.S. Prosser, Environment Canada / Canada Centre for Inland Waters; A.J. Bartlett, P. Gillis, V. Balakrishnan, Environment Canada / Aquatic Contaminants Research Division

Substituted phenylamine antioxidants (SPAs) are a group of chemicals on Canada's Domestic Substances List. They are high volume chemicals with a variety of uses, including: dye formulations, photosensitizers, lubricant antioxidants, viscosity improvers, and dispersants. SPAs are considered to be persistent, bioaccumulative, and inherently toxic. They can enter the environment in municipal wastewater effluents or via direct run-off from road surfaces. We investigated the chronic toxicity of four SPAs in a 21-day fathead minnow embryo-larval assay. Embryo-larval fathead minnow were exposed to SPAs in sediment because of SPA's affinity for organic matter. Reference sediment (2 % organic carbon) was spiked with 125, 250, 500, or 1000 μg/g of each SPA, and left for one month to equilibrate prior to fish exposures. Fathead minnow embryos and larvae were exposed in beakers with 35 g sediment and 700 mL lab water, with sediments and water renewed daily. Glass mesh-bottomed cups prevented direct contact of embryos and larval fish with sediment, and facilitated daily transfer to new exposure beakers. Endpoints were % survival to hatch, hatching success, deformities at hatch, survival til 8 and 16 days post-hatch (dph), and weight, length, and condition factor of larvae at 8 and 16 dph. All four SPAs decreased larval survival, with LC50s in the range of 250-350 μg SPA/g sediment. Water and sediment concentrations of SPAs are being measured to verify fish exposure concentrations. Concentrations of SPAs in sediment that affected survival of embryo-larval fish will be compared to measured concentrations of SPAs in biosolids and wastewaters from municipal wastewater treatment facilities in Canada.

WE120

Accumulation and maternal transfer of 2,2',4,4'-tetrabromodiphenyl ether (BDE-47) from an oral exposure in medaka fish (Oryzias latipes)

M. Gonzalez-Doncel, National Institute for Agricultural and Food Research and Technology / of the Environment; G. Carbonell, National Institute for Agricultural and Food Research and Technology / Department of Environment Laboratory for Ecotoxicology; S. Sastre, National Institute for Agricultural and Food Research and Technology / Department of Forest Ecology; E.M. Beltrán, INIA - National Institute for Agricultural and Food Research and Technology / Environmental; C. Gonzalez, National Institute for Agricultural and Food Research and Technology; C. del Río, INIA / Environment; J. García-Mauriño, School of Medicine / Cell Biology; C. Fernández, National Institute for Agricultural and Food Research and Technology / Department of Environment Laboratory for Ecotoxicology

In aquatic species, dietary exposure is the most environmentally realistic exposure route to contaminants with very low water solubility. Previous investigations conducted in our laboratory with post-hatch early developmental stages of medaka (*Oryzias latipes*) showed the capacity of 2,2',4,4'-tetrabromodiphenyl ether (BDE-47) to accumulate progressively during a 40-d oral exposure but without disturbing normal growth. Now, in this study effects assessment on reproductive capacity (i.e., fecundity and fertility) and BDE-47 accumulation were measured in adults and in resultant embryos and larvae from a 40-d maternal and paternal dietary exposure. Sexually mature medakas (165-d old) on a 3:2 male to female ratio were fed for 40 d with a diet containing 1000 ng BDE-47/g or with a control diet without BDE-47. At predefined time points (i.e. after 10, 20, 30 and 40 d since the start of the exposure), males and females were sampled and the eggs laid the same day were collected for a BDE-47 quantitative analysis. In addition, the reproductive capacity was assessed for the same time points and the resultant eleutheroembryos analyzed for BDE-47 content. The BDE-47 detected in embryos and eleutheroembryos ranged from 200 to 500 ng/g wet weight from 10 to 40 exposure days, respectively with levels comparable in embryos and eleutheroembryos. In the parents, the BDE-47 concentration was comparatively higher in males with respect to females. These differences correlated with the higher lipid content quantified in males. No significant effects on reproductive capacity were observed. This work was made possible by Spanish Government Grants CTM2013-44986-R and CTM2014-52388-R.

WE121

The evaluation of betamethasone as an endocrine disruptor using a fish model

J. Vestel, Merck & Co., Inc.

To date, little-to-no data have been collected on synthetic glucocorticosteroids in the environment and their potential endocrine disruption (ED) activity. They are antagonists to estrogen, but are expected to be found in higher concentrations in the environment due to higher therapeutic doses and a larger patient population. Steroid hormones have the potential to interact with the hypothalamic-pituitary-gonadal (HPG) axis and disruptions of this pathway can result in decreased reproduction and/or adverse developmental effects in offspring. Betamethasone, a synthetic glucocorticosteroid, has been on the market in the United States since 1983, and is on the WHO Model List of Essential Medicines. It mimics the action of cortisol and may disrupt the HPG axis. Studying fish for the ED potential of betamethasone is logical, as they could be exposed to pharmaceuticals in waste water treatment plant effluent following normal patient use and excretion. Additionally, fish have a much shorter time to reproduction and overall lifespan, making them ideal for determining lifetime, low-level chronic effects. Environmental modelling was used to estimate betamethasone concentrations in surface water and then environmentally relevant concentrations were then used in a two generation fish full life cycle (FFLC) study with Japanese medaka. Gross endpoints, as well as VTG and gonadotropin effects were evaluated in a tiered fashion.

Use of molecular and hormonal factors as biomarkers of Bisphenol A in Yellowfin Seabream (Acanthopagrus latus)

A. Negintaji, B. Archangi, Khorramshahr University of Marine Science and Technology / Marine Biology; A. Movahedinia, Khoramshahr university of marine science and technology / Marine Biology; A. Safahieh, Khoramshahr university of marine science and technology / Department of Marine Biology Faculty of Marine Science; N. Asadi, Khorramshahr University of Marine Science and Technology

Abstract Bisphenol A [BPA; 2,2-bis(4-hydroxyphenyl) propane] is an industrial important chemical that is abundantly used as a primary raw material for the production of plastics and resins. This substance is one of the most well-known endocrine disrupters widely released in aquatic environments mainly through urban and industrial sewage effluents; thereby posing a potential threat to the organisms in the ecosystems. In the present study, effect of BPA on liver DNA integrity, erythrocytic nuclear abnormalities (ENA) stimulus and thyroid hormone balance in male yellowfin seabream (Acanthopagrus latus) were investigated. For this reason, fish received intraperitoneal injections during a period of 2 weeks with 10, 50, 100 and 150 ug g-1 week-1 of BPA. Our results demonstrated a significant increase in fish micronuclei frequency after treatment with bisphenol A. In addition, the rate of liver DNA integrity was tested using the DNA alkaline unwinding assay. Results showed a decline in the rate of liver DNA integrity after 7 and 14 days of BPA exposure in comparison to the control group. In BPA treated fish, hepatic somatic index (HSI) rose in a dose-dependent manner ($R2 = 0.96$) after 7 days of treatment. Our results indicated significant reduction in plasma triiodothyronine (T3) and high levels of thyroxine (T4) in treated fish comparing the control groups. The findings of the project revealed that BPA strongly affected DNA and caused considerable breaks in strand of the living molecule. Additionally, erythrocytes are adversely damaged by BPA which is studied as ENA. Hence, it could be concluded that Micronucleus test and DNA strand breaks are sensitive cellular and molecular biomarker of BPA. Keywords: Acanthopagrus latus, Biomarker, Bisphenol A, Micronucleus test, DNA integrity, Endocrine disrupters, Thyroid hormones

WE123

The Effects of mixtures of androgenic and estrogenic chemicals on adult Murray River Rainbowfish

A. Miranda, School of Applied Sciences / School of Applied Sciences; A. Gregg, CSIRO Land and Water; A. Kumar, CSIRO / Center for Environmental Contaminants Research; V.J. Pettigrove, The University of Melbourne / Zoology; D. Nugegoda, RMIT University / School of Applied Sciences

When individual organisms and populations are exposed to Endocrine Disrupting Chemicals, it is likely that they are exposed to complex mixtures rather than to single chemicals. Studying the effects of single chemicals may not reflect the multitude of antagonistic or synergistic stimuli to which wildlife are subjected. A common source of both androgenic and estrogenic steroid hormones to the environment is the runoff resulting from animal feedlots. This is mainly due to the extensive use of anabolic implants in the beef industry. Implants have been used for more than 50 years due to their ability to increase the body protein content, growth efficiency and carcass weight and contain estrogens such as oestradiol (E2), progestins as progesterone and androgens such as trenbolone (TBL) acetate as ingredients. In the blood of livestock, administered trenbolone acetate is hydrolysed to 17β trenbolone and this by epimerization is then converted to 17 α trenbolone. Despite 17β trenbolone being a potent androgen receptor agonist with a 10 fold higher binding affinity, 17α trenbolone comprises about 95% of the total excreted product. The aim of this study was to evaluate the effects of 17α trenbolone alone and in combination with two endocrine disruptors of different modes of action, i.e. 17β oestradiol (50 ng/L) and Fadrozole (250 μg/L) on adult rainbowfish (*Melanotaenia fluviatilis*). The relative gene expression of steroid receptors in the liver as well as induction of vitellogenin in the plasma were used to assess potential effects. Results show that the expression of ERα and ERβ were significantly induced after exposures to TBL + E2 at both low (5ng/L) and high concentrations (500 ng/L) of 17 α trenbolone. The ERα expression in the TBL + E2 exposures correlated with the hepatic Vtg mRNA. The expression level of the ARβ was significantly reduced in the liver of *M. fluviatilis* when exposed to low concentrations of TBL in combination with E2 compared with controls, whereas when combined with high concentrations of TBL there were no significant differences. Vitellogenin induction was twofold lower when fish were exposed to E2 with a high doses of TBL than when E2 was mixed with a low dose of TBL. These findings demonstrate that E2 may have anti androgenic effects, leading to the down regulation of ARβ. In the aquatic environment where mixtures of androgens and estrogens are known to occur, similar counteracting effects are likely to occur.

WE124

Developmental effects of 2 and 6-hydroxychrysene on zebrafish embryos

G.d. Muller, UFSC / Biochemistry; G. Diamante, University of California, Riverside / Environmental Toxicology; A. Bainy, Universidade Federal de Santa Catarina / Bioquimica; F. Yamamoto, Universidade Federal do Paraná / Cell Biology; D. Schlenk, University of California-Riverside / Department of Environmental Sciences

Chrysene is one of most persistent polycyclic aromatic hydrocarbons (PAHs) present in crude oil. In the water column, chrysene likely undergoes photochemical oxidation potentially forming oxygenated photoproducts such as 2-hydroxychrysene (2-OH-chry) and 6-hydroxychrysene (6-OH-chry) in the water column. Previous *in vitro* studies showed that 6-OH-chry was an estrogen receptor (ER) antagonist, but 2-OH-chry was an ER agonist. Since dysregulation of estrogen pathways can cause abnormal fish development, the objectives of this study were to investigate the toxicity of chrysene photoproducts on embryonic development. For this purpose, *Danio rerio* embryos (2 hpf) were treated at several concentrations of 6-OH-chry (0.5-8 μM) and 2-OH-chry (0.5-5 μM) to determine percent survival and the occurrence of deformities at 76hpf. Survival after exposure to 2-OH-chry was not affected; however, treatment with 6-OH-chry significantly decreased survival. The LC50 value for 6-OH-chry was ±1.14 μM for a 74hr exposure. Significant differences in the occurrence of cardiac abnormalities were also observed. The EC50s for 6-OH-chry and 2-OH-chry were ±1.3 and ±0.64 μM, respectively. Despite the regio-selective differences in toxicity that was observed, co-exposure to an ER antagonist (ICI 182,780) or G-Coupled Estrogen Receptor (GPER) antagonist (G-15) did not affect the mortality and deformity percentages. Similarly, mRNA of GPER, or downstream transcription factors (Hand2; Lrrc10) was unaltered by hydroxyl-chrysene exposures. Since cardiac abnormalities due to PAHs are mediated through the Aryl hydrocarbon receptor (AhR), each compound was evaluated using an AhR transactivation bioassay, and neither compound showed AhR activity. Evaluation of embryos post-exposure indicated concentrations of 2-OH-chry, but not 6-OH-chry, in the yolk sac in a dose-dependent manner suggesting a potential regio-selective difference in the uptake or metabolism for each compound. Our findings indicate developmental toxicities of hydroxylated chrysenes may not be mediated through AhR or ER, but may be due to differences in embryonic clearance mechanisms.

WE125

ASSESSMENT OF THE RESPONSE ZEBRAFISH EMBRYOS TO ANALGESICS

A. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztatapalapa / Hidrobiologia Laboratorio Alejandro Villalobos

The pain medications are products that are consumed in large quantities worldwide. These drugs can cause harmful effects on aquatic organisms because they are designed to have a physiological effect at very low concentrations. The aim of this study was to determine the toxic effect of 6 types of analgesics: Acetylsalicylic acid, Ibuprofen, Diclofenac, Naproxen, Paracetamol and mixture of Naproxen and Paracetamol in zebrafish embryos, to evaluate their sensitivity. Static bioassays were performed with a duration of 48 hours, the embryos were exposed to 6 concentrations of drugs: 100, 75, 50, 25, 12.5 and 6.25 mg L^{-1} (12 replicates), plus a control without toxic. In the tests LC_{50} was determined and the degree of lipid peroxidation (TBARS) was evaluated. The toxicity of analgesics was (from highest to lowest toxicity): Diclofenac> Paracetamol> ibuprofen> mixture Naproxen and Paracetamol> naproxen> Acetylsalicylic Acid. The degree of lipid peroxidation was higher in embryos exposed to Paracetamol (83 nM MDA mg^{-1}) and the lowest in those exposed to acetilsalisilico acid (24.3 nM MDA mg^{-1}). Organisms exposed to sublethal concentrations (LC_{25} LC_{15}) during the recovery period, showed higher degrees of lipid peroxidation to that observed in control group at the start of the test, the majority of the embryos failed to hatch and died between the fourth to the seventh day.

WE126

Chronic exposure to pentachlorophenol alters thyroid hormones in zebrafish

G. Zhao, K. Li, China IWHR

Pentachlorophenol (PCP) is frequently detected in the aquatic environment and has been implicated as an endocrine disruptor in fish. Here, 4-month-old zebrafish(Daniorerio) were exposed to one of four concentrations of PCP (0.1, 1, 9 and 27 ?g/L) for 70 days. The effects of PCP exposure on plasma thyroid hormone levels, and the expression levels of selected genes were measured in the brain and liver. PCP exposure at 27 ?g/L resulted in elevated plasma thyroxine concentrations in male and female zebrafish, and depressed 3, 5, 3?-triiodothyronine concentrations in males only. In both sexes, PCP exposure resulted in decreased mRNA expression levels of thyroid stimulating hormone ?-subunit (tsh?) and thyroid hormone receptor ? (tr?) in the brain, as well as increased liver levels of uridinediphosphoglucuronosyltransferase(ugt1ab) and decreased deiodinase 1 (dio1). We also identified several sex-specific effects of PCP exposure, including changes in mRNA levels for deiodinase 2 (dio2), cytosolicsulfotransferase (sult1 st5), and transthyretin(ttr) genes in the liver. Environmental PCP exposure also caused an increased malformation rate in offspring that received maternal exposure to PCP. The present study demonstrates that chronic exposure to environmental levels of PCP alters plasma thyroid hormone levels, as well as the expression of genes associated with thyroid hormone signaling and metabolism in the HPT axis and liver, resulting in abnormal zebrafish development.

WE127

Effects of perfluorinated compounds on mitochondrial functions in early life stage of zebrafish (Danio rerio).

H. Shin, Seoul National University, Graduate School of Public Health / Department of Environmental Health Sciences; K. Choi, Seoul National University / School of Public Health; D. Jung, Seoul National School / Institute of Health and Environment

Perfluoroalkyl aicds (PFAAs) are well known surfactants that are widely used in industrial and consumer applications, and are persistent in the environment and biota. Many studies have elucidated their toxicological effects on various targets, including the liver, nervous and endocrine systems, and fetal development. This wide range of toxicological effects may be brought about from damages in the mitochondria, as well as mitochondria-mediated oxidative stress. In this study, we exposed zebrafish embryos to perfluorooctane sulfonate (PFOS), perfluorooctanoic acid (PFOA), and perfluorononanoic acid (PFNA) to investigate potential adverse effects on mitochondrial functions. Zebrafish embryos were exposed to five different concentrations (0, 250, 500, 1000, and 2000 μg/L) of PFOS, PFOA, and PFNA, respectively. Embryos were randomly collected from adult zebrafish and exposed to chemicals from 2hpf to 120hpf. Mortality, hatchability, and malformation rate were observed. At 120hpf, zebrafish larvae were collected and their gene transcriptions were analyzed. Total of 8 genes involved in electron transport chain (*cytb, atp5a1*, *coxI*, and *coxIV*) and oxidative stress (*gpx1, gstπ, hmox1,* and *sod2*) were examined. There were no changes in gene expressions of larvae exposed to PFOS or PFOA. However, altered expressions were observed for PFNA exposure groups. PFNA, at 1000 μg/L, significantly upregulated transcript levels of mitochondrial genes *cytb* and *atp5a1*, and of oxidative stress response genes *sod2* and *gstπ*. These initial results draws attention to potential effects low concentrations of PFNA have on various mitochondrial functions. Assessment of damages in the mitochondrial membrane and mitochondrial DNA are under way. This work was supported by NRF 900-20150033, Republic of Korea.

WE128

Effects of neuroactive pharmaceuticals on gene expression profiles in zebrafish embryos and larvae

C. Di Paolo, RWTH Aachen University / Ecosystem Analysis ESA; L. Sonnack, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology; M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; M. Fenske, Fraunhofer Gesellschaft IME / Translational Medicine and Pharmacology; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis

Neuroactive and neurotoxic contaminants present growing concern to fish, both at individual and population levels. Neuroactive pharmaceuticals in particular can modulate molecular neurological pathways and consequently interfere with population-relevant behavior at low concentrations. Ecotoxicological investigations of neuromodulation and neurotoxicity can benefit from molecular endpoints in fish, such as expression profiles of representative genes. In this study, we investigated the expression of a set of genes in zebrafish *Danio rerio* early life stages after static exposure to neuroactive pharmaceuticals. Zebrafish embryos and larvae up to 5 days post fertilization (dpf) were exposed to venlafaxine (serotonin norepinephrine reuptake inhibitor antidepressant), carbamazepine (voltage-gated sodium channel inhibitor and GABA receptor agonist anticonvulsant) and oxazepam (benzodiazepine derivative anxiolytic) at concentrations in the μg/L range (1 nM - 10 μM). These compounds are relevant aquatic contaminants, and selected concentration ranges are representative of environmental situations. Embryos and larvae were exposed for short (during 24 h) and prolonged (starting at day 0) exposure periods, simulating acute and chronic exposure scenarios. Afterwards, there was the evaluation of gene expression in embryonic (2 to 3 dpf) and larval (5 dpf) stages. Gene expression was quantified in pooled samples (n=24 fish) using Sybr Green based quantitative real-time PCR (qPCR). Target genes consisted of two set of genes, proposed as (i) markers of exposure to neuroactive compounds (e.g. *cfos*, *hspb11*, *fkbp5*) and (ii) markers of neuromodulation (e.g. *bdnf*, *neurog1*, *neuroD1*). Reference genes were *bactin*, *elfa* and *18s*. Exposure concentrations were measured at the beginning and at the end of exposure by LC-MS/MS. Results of this study are discussed regarding their ecotoxicological implications and the relevance for the annotation of adverse outcomes pathways. In addition, molecular endpoints are suggested for application in bioassays or as biomarkers in future ecotoxicological studies.

WE129

Development of an -omics based detection tool to discriminate between endocrine-mediated activity and systemic toxicity of substances.

S.U. Ayobahan, IME Fraunhofer / Department of Aquatic Ecotoxicology; E. Muth-Köhne, Fraunhofer IME / Ecotoxicology; M. Kotthoff, Fraunhofer IME / Environmental and Food Analysis; M. Teigeler, Fraunhofer IME / Ecotoxicology; C. Schaefers, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / Ecotoxicology

A mechanistic identification of the events preceding changes in vitellogenin expression is crucial to differentiate systemic toxicity from endocrine modes-of-action (MoA). An adverse outcome pathway (AOP) framework for endocrine MoAs shows that reduced vitellogenin concentrations lead to reduced fecundity and consequently, to a declining trajectory at the population level. Substances with other MoAs, exerting systemic toxicity, might also result in reduced vitellogenin, and thus lead to an identical adverse outcome (AO), although the molecular initiating event (MIE) is different. An improvement in determination tools is thus needed to ensure a reliable discrimination of endocrine disruptors from chemicals substances with other MoAs in order to avoid regulatory action and a further elongated higher-tier testing. The main aim of this study is to develop a method to discriminate between altered vitellogenin expressions as a result of systemic toxicity and endocrine disruption. In the present study, we apply iTRAQ proteomic labeling techniques and qPCR assays to quantify and validate genomic expression changes in zebrafish by means of quantitative analysis of respective proteins and peptides. Gonad samples and samples of other tissues treated with endocrine disrupting substance in comparison to the control samples are analysed by mass spectrometry-based approaches to identify regulated pathway and modifications of protein expression. The observed changes in endocrine-mediated MoAs will be compared with the MoAs arising from samples treated with substance leading to systemic toxicity. These improved approaches will allow identification and validation of specific MoAs and discrimination between different MoAs, which could not be distinguished by the standard approach due to an identical adverse outcome. QPCR analysis will be performed in order to determine if changes in mRNA expression are indicative for the triggered proteomic response. Candidate genes for this discrimination tool are *igf1, star and lss* genes related to steroid biosynthesis for determination of endocrine disruption or *lfabp10a, CYP2E1 and GSH* genes regulated due to systemic toxicity. The obtained results will provide a detailed understanding of a mechanistically-based alternative approach for hazard assessment.

WE130
Gene transcription profiles during the first 32 days of zebrafish development: thyroid, steroid, digestive and biotransformation systems
L. Vergauwen, E.D. Michiels, University of Antwerp / Zebrafishlab Dept Veterinary Sciences; E. Bagci, University of Antwerp / Zebrafishlab Dept of Veterinary Sciences; I. Gabriëls, J. Periz, University of Antwerp / Zebrafishlab Dept Veterinary Sciences; C. Pype, University of Antwerp / Department of Veterinary Sciences; E. Stinckens, University of Antwerp; E. Verbueken, S. Van Cruchten, University of Antwerp / Department of Veterinary Sciences; D. Knapen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences
The zebrafish has become an important model for ecotoxicity testing. Especially the zebrafish embryo is increasingly used for the development of alternative tests since early life stages of fish are not considered laboratory animals according to EU legislation. In addition to observing apical endpoints such as mortality, growth and reproduction, the focus on mechanistically understanding toxicity is increasing, e.g. in the context of AOP development. This demand is also increasingly supported by regulatory bodies. To better understand toxicological processes in early life stages it is essential to describe the reference state of healthy organisms. In this study we sampled zebrafish at 25 time points during development: 1.5; 6; 16; 24; 36; 48; 60; 72; 84; 96 and 120 hpf (hours post fertilization), and every two days from 5 until 32 dpf (days post fertilization). We analysed transcript levels of ± 40 genes involved in the thyroid, steroid, digestive and biotransformation systems using QPCR. While it is well known that these systems play a key role in both developmental and toxicological processes, the timing of activation of their specific components is poorly understood. For example, the biotransformation capacity of zebrafish embryos still is a topic of debate, and effects of endocrine disruptors on development have been demonstrated – however without properly described mechanisms. For the steroid system we studied the enzymes involved in steroid hormone biosynthesis, as well as the steroid receptors. With respect to the thyroid system, we included key regulators of the hypothalamic-pituitary-thyroid axis, thyroid hormone synthesizing and activating machinery, as well as thyroid receptors. We analysed the exact timing of activation of different digestive enzymes (carbohydrates, lipids and proteins) which is especially important for understanding the transition to free-feeding larvae. For the biotransformation system, we studied Phase I (Cytochrome P450) but also Phase II metabolizing enzymes and drug transporters. In addition to providing information on gene activation, our data shed light on potential maternal transfer of specific mRNAs. This library of zebrafish gene transcription profiles is intended to function as a reference both for fundamental developmental studies, as well as for toxicological studies.

WE131
Using Multi-Omics Measurements to Distinguish Contaminant Responses in a Zebrafish Model
S.S. Huang, Axys Analytical Services Ltd. / Metabolomics; J. Benskin, Stockholm University / Environmental Science and Analytical Chemistry; B. Chandramouli, AXYS Analytical Services, Ltd; J. Cosgrove, AXYS
Environmental monitoring of chemical effects is challenging due to the ever increasing number of chemicals and the complexity of environmental samples. Conventional toxicity testing using whole animal organisms provides critical information on biological responses; however, morphological parameters such as growth and survival may not be sensitive enough to detect adverse effects of sublethal exposures, a scenario which is more ecologically relevant. In comparison, the ability to detect changes at the RNAs, proteins, and/or metabolite levels with techniques such as transcriptomics and metabolomics can generate high-throughput and sensitive early indicators of potential sublethal effects. Recently, zebrafish (*Danio* rerio) embryo has gained considerable interests through OECD and REACH initiatives as an alternative and equivalent toxicity testing version to the adult stage. As early developmental stages are critical and sensitive to environmental perturbations, the combination of zebrafish larvae and multi-omics technologies can be a powerful tool in characterizing early indicators of chemical insults. In this study we utilized a combined targeted metabolomics and transcriptomic approach to evaluate contaminant toxicity in a zebrafish larvae model. Zebrafish larvae (96 hpf) were exposed to a wide classes of contaminants including pharmaceutical and personal care products and heavy metals at environmentally relevant concentrations for a 24h period. Quantitative real-time PCR were performed on over 40 target genes covering a wide range of biological systems to assess transcriptomic effects. At the same time, over 217 metabolites, including acylcarnitines, amino acids, glycerophospholipids, ∑hexose, sphingolipids, biogenic amines, fatty acids, and bile acids, were also quantitatively measured by LC-MS/MS and FI-MS/MS to determine the effects on the metabolome. The unique molecular signature response may be used to inform the types of toxicants present in the environment. Furthermore, this integrated OMICS approach can better inform the chemical modes-of-actions and allows a systems biology approach in identifying key trajectory that may lead to adverse health outcomes for exposed animals.

WE132
Toxic effects of sediments contaminated with metals in the zebrafish Danio rerio
A. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos; A. Fonseca-Meraz, Universidad Autonoma Metropolitana Iztapalapa
Heavy metals have as their main source of anthropogenic activities being the sediments one of main reservoirs of these elements, acting as sources of pollution by providing metal to the water column, which constitutes a threat to aquatic biota. Because there are few studies of the effect of sediments contaminated in fish, the aim of this study was to evaluate the toxic effect of sediments contaminated with Cd, Cu and its metals mixture on zebrafish. Bioassays were performed. The organisms were exposed to 3 sediment samples: 2 samples spiked with metals Cd (5 mg L^{-1}) and Cu (2.5 mg L^{-1}) and the third with the mixture of the two metals, for 20 days, plus a control group. At the end of the exposure period 5 organisms were taken at random from each experimental group, Its weight was evaluated and the following biomarkers: lipid peroxidation (MDA levels), and frequency of micronuclei. The results show that the rates of increase in weight of the organisms exposed to contaminated sediments, had negative values, indicating that fish lost biomass. Fish exposed to sediments contaminated with Cadmium and the mixture of metals showed higher levels of lipid peroxidation, (43.9 and 37.1 nM MDA g^{-1} respectively). The highest frequency of micronuclei (0.075%) was observed in organisms exposed to the mixture of metals. The results of this study indicate that sediments contaminated with metals cause adverse effects on organisms living in the water column.

WE133
Reactive oxygen species (ROS) quantification as an endpoint in mixture toxicity analysis with the zebrafish embryo (Danio rerio)
E. Küster, Helmholtz Centre for Environmental Research, Dept.Bioanalytical Ecotoxicology / Bioanalytical Ecotoxicology; M. Kalinowski, K. Luehmann, Helmholtz Centre for Environmental Research- UFZ / Bioanalytical Ecotoxicology; E. Grabinska-Sota, Silesian University of Technology; A. Jakubowska, Silesian University of Technology / Environmental Biotechnology Department
Reactive oxygen species (ROS) serve as signaling molecules and are also a general side product of metabolism. The concentrations of ROS are counterbalanced by a group of antioxidant molecules and enzymes as increased concentrations will damage proteins, DNA and lipids and finally could lead to death of organisms due to oxidative stress. The embryos of the zebrafish are now an established model organism in ecotoxicology serving both as a tool for mode of action analysis and as a fish test alternative for regulatory and monitoring purposes. Some literature exists which already use the embryos or larvae of the zebrafish in immunological research. In the following work the existing published protocols were adapted to the use of the zebrafish embryo in ecotoxicology testing as described by the OECD 236 guideline. The different developmental stages of the embryos and eleutheroembryos from 2 to 96 hours post fertilisation (hpf) were analysed without and with ROS producing substances by the use of the fluorescent dye 2,7- dichlorodihydrofluorescein diacetate. The organism might show age and substance dependent different sensitivities and reactions to oxidative stressors. Substances known for their ROS generating potential served as positive controls (e.g. hydrogen peroxide, tert-butyl hydroperoxide (TBHP), rotenone and CdCl2) to evaluate sensitive time windows for exposure. The increased fluorescence due to oxidative stress was analysed on whole organisms in kinetic mode over a duration up to 6 hours in 96 well micro titer plates and with a fluorescence photometer. Depending on age and substance an increase in fluorescence could be observed within min (hydrogen peroxide) or only after many hours (TBHP). The reactions (in terms of relative fluorescence unit increase) ranged between 70 and 300 % of control embryos and the test proved to be suitable for the analysis of multiple samples in parallel within a maximum of 6 hours. Results will be presented also in the view of usage of the ROS-test for mode of action analysis of similar and dissimilar acting substances in mixtures of environmental contaminants.

WE134
Effects of Microcystis aeruginosa and the toxin microcystin-LR on target gene expression profiles and histopathological changes in larval zebrafish Danio rerio
D. Sabrei, Heriot-Watt University / School of Life Sciences; K.M. Henry, Tetra Tech EM, Inc. / School of Life Sciences
Microcystis aeruginosa is a cyanbacterium that can produce the hepatotoxin microcystin-LR (MC-LR) and that is responsible for many harmful algal blooms (HABs) in freshwaters. Blooms of *M. aeruginosa* frequently occur in eutrophic surface waters, and the presence of the cyanobacteria and toxins can become an important problem for ecological and human health. We have found that toxicity

in the zebrafish *Danio rerio* includes effects that are independent of the toxin. Our objectives are to investigate changes in target gene expression profiles in zebrafish larvae in relation to concentration and duration of exposure to *M. aeruginosa* and MC-LR, and to investigate the histopathology changes that could happen to the larvae during the exposure. We have cultured a toxin-producing strain and a non-toxin-producing strain of *M. aeruginosa* to generate a supply of lyophilized cyanobacterial cells characterized for use in toxicity tests. Zebrafish larvae (age 72 h post fertilization) were exposed to lyophilized *M. aeruginosa* or MC-LR for 96h at sub-lethal concentrations (5, 25, 50, 100, 200, 400 μg MC-LR/L). Also, another set of zebrafish larvae were exposed to MC-LR or *M. aeruginosa* at concentrations of 5, 50 μg MC-LR/L, and the larvae were sampled after different exposure durations (4, 24, 48, 72, 96 h). Survival of larvae was recorded, histopathology conducted, and changes in expression of target genes were investigated by quantitative PCR (Q-PCR) for the following genes: catalase (*CAT*), superoxide dismutase1 (*SOD1*), glutathione peroxidase (*GPx*), glutathione-S-transferase (*GST*), protein phosphatase (*PPP1, PPP2A*), vitellogenin (*VTG*), and cytochrome P450 (*CYP1A*). We anticipate that these results will enhance understanding of the molecular responses and the histopathological changes in fish during the progression of exposure to a HAB caused by *M. aeruginosa*. **Key words:** *Microcystis aeruginosa*, microcystin-LR, Gene expression, Zebrafish.

WE135

Detection of cholinesterase inhibitors in water samples from Novi Sad (Serbia) using effect-directed analysis

R. Massei, S. Seidensticker, Helmholtz Centre for Environmental Research UFZ; T. Schulze, M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis; W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis; E. Küster, Helmholtz Centre for Environmental Research, Dept.Bioanalytical Ecotoxicology / Bioanalytical Ecotoxicology

Organophosphates and carbamates are commonly used as insecticides in agriculture, residential landscaping, public recreation areas and in public health pest control programs. The main known mode of action is the inhibition of cholinesterases (ChE) and the subsequent increase of acetylcholine in the synaptic cleft. For many of these substances the structure and fate is well characterized and they are routinely monitored in order to detect their concentrations in the ecosystems. The presence of organophosphates and carbamates in the environment can cause several problems and distress in the aquatic life such as malformations, damage to the nervous system and reproduction problems. Despite the clear mode of action (MoA), many factors could influence the results of an *in vivo* test of environmental samples during the analysis of AChE activity: mixture effects, developmental delay, malformations and the presence of other compounds with different MoA (e.g. dioxin-like compounds) are only some of the factors that could influence the bioassay. The complex environmental mixture could mask the effect or lead to false positive results. However, effect directed analysis (EDA) can identify masking effects, unravel the presence and identity of primarily causative chemicals by combining chromatographic fractionation, chemical analysis and biotesting. In this study, water samples of the river Danube (Novi Sad, Republic of Serbia) were collected using large volume SPE device with a polymeric sorbent. Chemical analysis with LC/HRMS showed presence of organophosphates in the parent sample of untreated wastewater. The sample was subsequently fractionated using a HPLC with a reversed phase semi-preparative C18 column and 26 fractions were collected. Preliminary results are showing a clear inhibition of AChE (20% compared to negative control) in only one out of 26 fractions. This study is trying to elucidate the contribution of the use of ACHE enzyme activity inhibition of substance groups like organophosphates and carbamates in the frame of *in vivo* testing of environmental (mixture) samples and EDA studies with *Danio rerio* embryos.

Effect-directed analysis of atmospheric particulate matter

S.R. Mesquita, IDAEA-CSIC & FCUP & CIIMAR-UP / METOX Coastal and Marine Environmental Toxicology; B.L. van Drooge, IDAEA-CSIC; C. Barata, CSIC / Environmental Chemistry; N. Vieira, Faculty of Sciences Porto University; L. Guimaraes, CIIMAR University of Porto / METOX Coastal and Marine Environmental Toxicology; B. Pina, IDAEA-CSIC / Department of Environmental Chemistry

Atmospheric particulate matter (PM) is a recognized risk factor for the global burden of disease in human populations and a widespread threat to all living organisms. PM is primarily emitted from combustion processes and comprises a significant fraction of organic compounds, such as polycyclic aromatic hydrocarbons (PAHs). If specific tools could be developed to promptly discriminate the toxic potential of PM, based on the mode of action of its constituents, rather than on PM mass and BaP concentrations which are currently used in air quality legislation, a more straightforward approach to air quality management could be accomplished. Therefore, our main objective was to investigate the toxicity of the organic fraction of atmospheric PM and provide a cost-effective approach that could be easily applied to diagnose potential toxicity of exposure to this fraction. To tackle this objective, a general strategy was adopted, in which a yeast-based assay for dioxin-like activity (AhR-RYA), and the zebrafish embryotoxicity assay (ZET assay) followed by molecular tools, were used to evaluate biological effects elicited PM1 (PM< 1 µm) organic extracts from the city center of Barcelona. This study also clarified whether the effects observed can be further assigned to primary or secondary PM organic components, and whether time differences (day vs. night, working days vs. weekends) translate into distinctive effects of PM constituents. The work developed lead to the major conclusion that the AhR-RYA and the ZET are valuable assays for effect-directed analysis of ambient PM, also allowing to study the mode of action of PM organic fraction. Integrated results from different surveys from diverse sampling points suggest that physiological effects are strongly dependent on the chemical composition, particle size distribution, and, ultimately, the emission sources of PM. On the contrary, total PM mass and BaP concentrations appeared as poor predictors of potentially adverse biological effects. Therefore, effect-directed air quality assessment would likely represent a major improvement on PM toxicity evaluations. The authors acknowledge the CTM project (CTM2014-51985-R), and the Portuguese Foundation for Science and Technology for the doctoral grant of S.R. Mesquita (SFRH/BD/80710/2011) funded by the Program POPH-QREN through the Portuguese Ministry of Education and Science and the European Social Fund, and support through project PEst-C/MAR/LA0015/2013.

Development of a refined zebrafish feeding trial

I. Gabriëls, L. Vergauwen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences; M. De Boevre, Ghent University UGent; S. De Saeger, Ghent University UGent / Department of Bioanalysis; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; M. Eeckhout, Ghent University UGent / Department of Applied Biosciences; M. De Loose, Institute for Agricultural and Fisheries Research ILVO / Technology and Food Science Unit; D. Knapen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences

Fish feeding trials are important for investigating foodborne ecotoxicological exposure as well as for evaluating food safety. Although a dietary biomagnification fish test exists, a standardized fish oral toxicity test is currently not available. Safety of food components, additives and contaminants is generally evaluated using rat feeding trials to assess (repro)toxicity. The development of a refined zebrafish feeding trial would advance existing testing strategies by reducing the cost, by replacing the use of mammals/birds by a lower vertebrate species, and by facilitating reproductive and multigenerational studies. When testing food, substitution of part of the food by the component under evaluation is often required, possibly interfering with nutritional requirements. Therefore, the extent of component substitution which can be processed by the zebrafish metabolism (maximum tolerable percentage) should be assessed prior to the component evaluation trial. Since we will conduct a feeding trial with GM maize later on in our study, we defined the maximum tolerable percentage of maize. First, we formulated experimental fish feeds based on the composition of commercial fish feeds. Maize was introduced in the feed by a stepwise substitution of a wheat component (25% of the whole feed). We compared 6 experimental feeds to three different commercial feeds in a one month feeding trial, during which we investigated the following endpoints: condition factor and growth, hepatosomatic and gonadosomatic index (HSI and GSI), reproduction, energy budget and feed digestibility. The growth of fish fed with 25% wheat or 25% maize slightly decreased. The HSI of males increased with increasing percentage of maize. Feed digestibility analysis showed a decrease in carbohydrate uptake when fish were fed with an increasing percentage of maize substitution. Based on these results, we selected a 15% maize substitution for conducting the GM maize feeding trial. This selection was based on two criteria: (1) the biological limits of the maize component in the zebrafish feed should be respected, (2) the amount of maize substitution should allow us to observe effects of GM maize if there are any. We suggest that our approach of determining component substitution rates before carrying out feeding trials could be a valuable asset when evaluating food safety, as well as for investigating dietary ecotoxicological exposure of fish.

WE138

Comparison of Different Feeding Diets to Improve the Performance of Higher-Tier Fish Tests

J. Baumann, Eurofins Agroscience Services EcoChem GmbH / Aquatic Toxicology; J. Wiewel, C. Tanneberger, A. Knoch, Eurofins Agroscience Services Ecotox GmbH / Aquatic Ecotoxicology; G. Gonsior; C. Hafner, Eurofins Agroscience Services Ecotox GmbH / Aquatic Ecotoxicology

For the testing of endocrine functions of substances, the demand for higher-tier/ multi-generation fish tests like the MEOGRT (OECD 240) constantly growths. Such tests usually investigate at least one complete generation cycle of the F1 generation. The first two to three weeks post hatch is the most sensitive and critical phase. Feeding during this period of time is crucial for the development of fry and therefore the successful performance of the tests. Since higher-tier fish tests are time consuming and complex, feeding of fish should be kept as simple as possible. Therefore, artificial foods like micro flakes are often the preferred foods of choice. However, our results showed that artificial foods were not sufficient for the sole feeding of fry. The Early Life Stage Test (ELS; OECD 210) is a 35-day-test which exactly covers the critical first life stages of fish and therefore is greatly suitable to investigate development of fry. In order to investigate the optimal diet for fry in our higher-tier fish tests, we performed several ELS tests according to OECD guideline 210 with the Zebra fish *Danio rerio* in a flow-through system. We compared different diets consisting of commercial micro flake and liquid fry food, hole egg suspension, different living brine shrimp species and decapsulated brine shrimp, rotifers and combinations of these. After 35 days survival, growth and weight were compared. The tests showed that Zebra fish fry was too small to feed on most artificial foods. Further treatment like grinding was necessary increasing time for preparation. Our results indicated a significant preference for natural diets like brine shrimp and rotifers with most survival rates higher than 90 %. The poster will compare the results of the different diets and give hints on which diet may be preferred in higher-tier fish tests. Furthermore, the existing validity criteria of standardized higher-tier fish tests will critically be reviewed in comparison to our findings.

WE139

Xenobiotic metabolism in alligator gar (Atractosteus spatula): A comparison with rainbow trout (Oncorhynchus mykiss)

K.M. Johanning, KJ Scientific LLC / dba of Pura Vida Connections LLC; H. Segner, University of Bern / Centre for Fish and Wildlife Health; B.W. Brooks, Baylor University / Environmental Health Science Program Department of Environmental Science; S. Burket, Baylor University; Q. Fontenot, Nicholls State University / Biological Sciences Department; A. Ferrara, Nicholls State University / Biological Sciences

Metabolic stability determines the extent to which xenobiotics are biodegraded. One of our interests is pharmaceutical compounds, which are chemicals of emerging concern in aquatic environments. Information on the chemical metabolism can be used to determine bioaccumulation potential or BCF (Bioconcentration factor) that is used for regulatory purposes in REACH (Registration, Evaluation, Authorization and Restriction of Chemicals). Under this initiative, chemicals are regulated and must be tested for PBT (Persistency, Bioaccumulation and Toxicity). The trout *in vitro* metabolism assay is a new *in vitro* methodology to test for bioaccumulation in the PBT assessment. This assay is undergoing validation through the OECD (OECD Project 3.13) and is gaining acceptance among regulatory agencies. The *in vitro* trout metabolism assay decreases the number of animals used for testing, testing costs and time required to obtain results. Despite of the advances in this and other methodologies, we must evaluate *in vitro* metabolism assays across a variety of species to better understand interspecies variation and differences in how species function under different or environmentally relevant conditions such as dissolved oxygen concentrations and temperatures. The objective of this research was to compare *in vitro* metabolism in the liver S9 fraction of alligator gar to rainbow trout as our reference species. Alligator gar is a unique ancient fish that provides a valuable contrasting model to rainbow trout. Alligator gar live at higher temperatures and lower dissolved oxygen levels than rainbow trout. Differences may be found in how these two species do or do not metabolize xenobiotics. Laboratory or hatchery raised alligator gar and rainbow trout were maintained at 23?C and 13?C, respectively. Fish were acclimated to laboratory conditions for at least one-month prior to sacrifice. Fish were euthanized and livers from alligator gar and rainbow trout were perfused with a saline buffer (HBSS) at pH 7.8. After each perfusion, liver S9 fractions were prepared following protocols established for rainbow trout (Johanning et al., 2012). Phase I and II enzyme activities for both species were compared. Thus far, EROD and GST activities appear to be comparable. Experiments are ongoing to further compare metabolism by these enzymes and metabolism of pharmaceuticals to explore evolutionary strategies and adaptations at the physiological level.

WE140

Endocrine disruptor risk evaluation in vivo with transgenic zebrafish larvae indicating glucocorticoid signaling activity

M. Macherey; B. Weger, Nestlé / Institute of Health Sciences; M. Weger, University of Birmingham / Institute of Biomedical Research; T. Dickmeis, ITG/KIT / Institute of Toxicology and Genetics ITG

Glucocorticoids (GCs) are steroid hormones with important functions in metabolism and stress response. Synthetic GCs have immuno-suppressive, anti-inflammatory and anti-allergic properties and are widely prescribed for the treatment of diseases such as asthma and rheumatoid arthritis. These drugs are released into the environment due to incomplete removal by waste water treatment plants, and remarkably high concentrations were detected in receiving rivers. Acting as endocrine disruptors, these and other compounds may interfere with the hormonal system of wildlife, calling for *in vivo* tests measuring GC activity. Currently available test systems are centered on *in vitro* reporter gene bioassays with transgenic cell cultures. In contrast, bioassays with zebrafish larvae enable risk assessment in the whole, living organism. Our ***G**lucocorticoid* **R**esponsive **I**n vivo **Z**ebrafish **L**uciferase activit**y** (**GRIZLY**) assay allows us to investigate activation or inhibition of GC signaling *in vivo*, taking into account effects such as metabolization of compounds or organ specific effects.The assay is based on a transgenic line (*GRE:Luc*) carrying a luciferase reporter gene under control of four GC response elements (4xGRE). Comparison with a zebrafish cell line carrying the same reporter construct helps to pinpoint indirect or metabolism-related *in vivo* effects of a sample. The **GRIZLY** assay identified known activators of GC signaling, including the environmental contaminants dexamethasone, prednisolone and prednisone, in a chemical library of pharmaceutical compounds. It also detected pregnenolone, which stimulates endogenous cortisol production and, therefore, was active only in the larval assay. When screening for inhibition of GC signaling, we again found compounds active *in vitro* and *in vivo* as well as numerous substances only active *in vivo*. Importantly, the test can equally be modified to specifically target compounds interfering with endogenous GC biosynthesis. Strikingly, several drugs so far not implicated in interfering with GC signaling were identified by the larval assays. Deeper investigations of their underlying modes of action are in process. These results point out that interference with GC signaling and biosynthesis needs more attention in environmental risk assessment of compounds, and that *in vivo* testing is indispensable for this. Our test system covers these needs, allowing rapid whole-organism testing with high sensitivity and specificity.

WE141

Linking gene induction to physiological effects using transgenic medaka

P. Spirhanzlova, MNHN; P. Trebulle, J. Lallement, C. Bergounhou, A. Sébillot, Watchfrog SA; A. Kanamori, Nagoya University; B. Demeneix, Evolution of endocrine regulation, MNHN; G. Lemkine, A. Tindall, Watchfrog S.A.

Gonadal development in medaka (*Oryzias latipes*) is dependent on the synergy between oestrogens and androgens. Any disruption in steroid hormone levels can cause the induction of ovo-testis, a clear indicator of sex reversed germ cells. To determine the sensitive windows for hormonally induced sex reversal in medaka, we developed a novel 42sp50-GFP_ChgH-GFP transgenic medaka line. This line allows the identification of ovo-testis by fluorescence (GFP) present in developing oocytes and in parallel allows quantification of oestrogen axis activity via GFP in the liver. Germinal transgenesis resulted in a stable line exhibiting strong GFP signal in the ovaries and liver in response to oestrogens. To identify the sensitive developmental period to exogenous agents, fry were exposed to 24 hour pulses of oestradiol (E2; 500μg/L), dihydrotestosterone (DHT; 2.5μg/L or 500μg/L) or flutamide (5mg/L) at various time points between day post fertilisation (dpf) 1 and 12. Evaluation of phenotype followed by genotyping at dpf 16, revealed sensitivity to E2 between dpf 1-5 and two periods of increased susceptibility to DHT or flutamide between dpf 0-1 and dpf 5-8. No phenotypic sex reversal was detected after the exposure to DHT or E2 on dpf 11 or dpf 12 respectively. We show the relative sensitivity of early developmental stages to the induction of ovo-testis in XY and XX medaka and that our newly developed 42sp50-GFP_ChgH-GFP medaka line is a suitable model for studying this phenomenon.

WE142

Synthetic progestins disrupt the glial cell specific-brain aromatase expression in the developing brain of fish

C. Garoche, INERIS; J. Cano-Nicolau, University of Rennes 1 / IRSET; J. Porcher, INERIS / INERIS UMRI SEBIO ECOT; O. Kah, Universtiy of Rennes 1 / IRSET; F. Brion, INERIS / Ecotoxicology Unit

Few studies have addressed the biological effects of natural and synthetic ligands of the nuclear progesterone receptor (nPR) on fish development and reproduction, resulting in a significant lack of data to assess the hazard and risk posed by these compounds on aquatic organisms. Yet progesterone plays key roles in many vertebrates and recent data showed that some progestins are present in the aquatic environment at concentrations that can impair reproduction. In light of this context, we studied the effects of progesterone and a panel of synthetic nPR ligands on the estrogen-receptor (ER)-signaling pathway by investigating the expression of the zebrafish brain aromatase *cyp19a1b* gene using zebrafish-specific mechanism-based *in vitro* and *in vivo* assays. Twenty-four nPR ligands were screened on transgenic *cyp19a1b*-GFP zebrafish embryos to assess their potential estrogenic effect. Progesterone and its isomer dydrogesterone as well as drospirenone and all the progesterone-derived progestins had no effect on GFP expression. However, all progestins derived from 19-nortesterone induced the *cyp19a1b* expression in an ER- and concentration-dependent manner with EC_{50} ranging from the low nM to the μM range. These results show that progestins are estrogenic to fish and that early-life exposure of fish to 19-nortestosterone disrupts the ER-signaling pathway within the developing brain. The 19-nortestosterone derived progestins levonorgestrel and norethindrone were further tested in U251-MG cells transfected with any of the three zebrafish ER subtypes zfERα, zfERβ1, or zfERβ2. Progesterone had no effect on luciferase activity with either of the zfER subtypes. Norethindrone and levonorgestrel both induced luciferase activity that was blocked by co-exposing the cells with ICI 182,780. An ER competition assay showed that both progestins were unable to bind to and activate ER except at very high concentrations (10^{-5}M), suggesting they require metabolic activation prior to elicit estrogenic activity. This study highlights the relevance of using zebrafish-specific screening assays to characterize endocrine disrupting properties of emerging contaminants and demonstrates that 19-nortestosterone derived progestins are pro-estrogenic compounds targeting radial glial cells inducing *cyp19a1b* expression in the developing brain of fish. Given that ER signaling is one of the very first to emerge during early-life stage development, the consequences should be further investigated.

Nonylphenol impairs development of the olfactory bulb by altering projection networks of estrogen responsive cells in the forebrain

A. Takesono, University of Exeter / Bioscieces; J. Green, University of Exeter / College of Life and Environmental Sciences; A. Scott, University of Exeter / Biosciences College of Life and Environmental Sciences; S. Mourabit; T. Kudoh, University of Exeter / Biosciences College of Life and Environmental Sciences; C. Tyler, Biosciences College of Life and Environmental Sciences

We have established an estrogen biosensor transgenic zebrafish (ERE-TG fish) that detects tissue responses to estrogenic chemicals via expression of fluorescent reporter proteins.. Using the ERE-TG fish, we have observed that specific subsets of cells in the forebrain are responsive to estrogens, however, the role(s) of estrogen signalling in development and function(s) of these cells are not known. We observed two types of estrogen responsive cells in the forebrain cells from the early onset of neurogenesis in the ERE-TG embryo, one localised in olfactory bulb with complex projection networks and another in telencephalon showing a characteristic polar morphology with a radial process. These estrogen responsive cells were not immunoreactive for neuronal markers (acetylated tubulin and HuC), but expressed a neural progenitor marker Sox2, suggesting specific roles of estrogen signalling in the neural progenitor development/ function(s). We investigated the spatiotemporal relationships between olfactory sensory neurons and estrogen responsive olfactory progenitor cells, applying fluorescent *in situ* hybridization for olfactory bulb neuron specific markers (lhx2 and tbx21) and immunohistochemistry against the ERE reporter (mCherry). Estrogen responsive olfactory cells were localised at spatially distinct regions from those of lhx2 or tbx21 positive cells but their projections innervated directionally towards lhx2 and tbx21 expressing cells, suggesting the estrogen responsive olfactory bulb cells may play role(s) the development/function(s) of lhx2 and tbx21 positive olfactory sensory neurons. Interestingly, exposure to an endocrine disrupting chemical (nonylphenol, NP) markedly inhibited the establishment of projection networks of the estrogen responsive olfactory cells, which showed shorter projections and ectopic distributions of the cell bodies. NP did not alter the spatiotemporal expression of lhx2 or tbx21 but impaired the innervation of estrogen responding olfactory cells to Lhx2 and tbx21 positive cells. NP also reduced significantly the size of olfactory bulb/forebrain. Taken together, our findings indicate estrogen responsive cells in the forebrain possess fundamental roles in olfactory bulb developmentand the environmental oestrogen NP may affect brain development during embryogenesis by impairing development of estrogen responsive olfactory cells and their spatiotemporal networks.

Wildlife ecotoxicology: from food chain exposure to population effects (P)

Effects of Persistent Organic Pollutants on Vitamin A Levels in Faroese Pilot Whales

K. Hoydal, University of the Faroe Islands / Research; A. Arukwe, T.M. Ciesielski, Norwegian University of Science and Technology / Department of Biology; R.J. Letcher, National Wildlife Research Centre / Ecotoxicology and Wildlife Health Division; M. Dam, Environmental Agency; B. Jenssen, Norwegian University of Science and Technology / Biology

Long-finned pilot whales (*Globicephala melas*) are highly exposed to persistent organic pollutants (POPs), such as those classified as organohalogen contaminants (OHCs). POPs are known to interfere with the regulation and homeostasis of retinoids (vitamin A and its metabolites). Retinoids are lipophilic molecules essential for vision, growth, reproduction, immune function and cellular division and differentiation in mammals. Disruption of retinoid homeostasis can thus lead to impairment of these functions in mammals. OHCs and their metabolites can interfere with retinoids by different mechanisms including the disruption of vitamin A metabolism. The CYP26 enzyme is involved in the metabolism of retinoids by catalysing the oxidation of retinoic acid to polar metabolites. Effects of POP exposure on vitamin A in pilot whales were presently studied by analysing correlative relationships between the concentrations of selected OHCs (PCBs, OCPs and PBDEs) and retinoids in plasma and liver and *cyp*26 mRNA expressions in liver of the pilot whales. The results showed that *cyp*26a1 mRNA expression, but not *cyp*26b1 expression, was inversely correlated to all analysed POPs (r_s0.543, $p< 0.05$). The higher retinol levels with increasing POP concentrations in plasma could indicate increased mobilisation of retinol, although the effect was not detected in the liver stores.

WE145

Contamination of farmland bird's eggs by present and past plant protection products - the grey partridge as a case study

E. BRO, ONCFS / Wildlife Research; J. Devillers, CTIS; F. Millot, ONCFS; A. Decors, ONCFS / SAGIR Network

Farmland birds are in decline in Europe. The contamination of their eggs by currently used plant protection products (PPPs) is poorly documented despite a potential to adversely impact their breeding performance. In this context, 139 eggs of 52 grey partridge *Perdix perdix* clutches were analysed using GC/MS-MS and LC/MS-MS screenings measuring ca. 500 compounds at a LoQ of 0.01 mg/kg. A total of 15 different compounds were detected in 24 clutches. Nine of them are currently used by farmers as fungicides (Difenoconazole, Tebuconazole, Cyproconazole, Fenpropidin, and Prochloraz), insecticides (lambda-Cyhalothrine and Thiamethoxam/Clothianidine), and herbicides (Bromoxynil and Diflufenican). Mixtures were less detected than expected by potential exposure. We could associate a contamination and a probable exposition (field treatment) in several cases. Some older PPPs were also detected (Fipronil (+sulfone), HCH (a,b,d), Diphenylamine, Heptachlore (+epoxyde), DDT (Sisomers)), as well as PCBs. Concentrations ranged between < 0.01 and 0.05 mg/kg, but reached 0.067, 0.11, and 0.34 mg/kg in three cases. Our results testify a contamination of females and/or their eggs to PPPs in operational conditions, as well as to organochlorine pollutants or their residues, banned inFrancesince years, even decades, that persistently contaminate the environment. We discuss the possible routes of exposure, the probability to detect a contamination in the eggs, and the prevalence of such a contamination by means of multicriteria analysis. Unfortunately, although the wealth of information collected and analysed, it remains difficult to conclude about effects on egg / embryo characteristics yet, and additional investigations are needed. Lastly, we share our experience from our case study to document unintentional effects of PPPs on the breeding success of wild birds in the real world. This work was supported by the research programme *Pesticides* funded by the French Ministries in charge of Ecology and Agriculture with a financial support from ONEMA. Funds issue from the fees on diffuse pollution.

WE146

Exposure of Red Kite nestlings to chemicals and consequences on health

M. Coeurdassier, University of Franche-Comte / UMR ChronoEnvironment; N. Crini, University of FrancheComte / Department ChronoEnvironment UMR UFCCNRS; N. Bassin, T. Powolny, University of FrancheComte / ChronoEnvironnement; I. Fourel, VETAGROSUP; R. Mateo, U.C.L.M.-C.S.I.C. / Instituto de Investigacion en Recursos Cinegeticos; R. Scheifler, University of Franche-Comte / ChronoEnvironnement; G. Faggio, Conservatoire des Espaces Naturels - Corse; C. Fritsch, CNRS / UMR ChronoEnvironnement; A. Mionnet, LPO Champagne-Ardennes; C. Morin, LPO Franche-Comté; R. Riols, LPO Auvergne; T.G. Pottinger, Centre for Ecology and Hydrology; F. Criscuolo, S. Zahn, IPHC

The Red kite is a European endemic raptor listed as "Near-Threatened" by the IUCN. Poisoning by pesticides is considered one of the major threats for kites and they can be exposed to metal(loid)s, and/or POPs. Within the framework of the French National Action Plan, some breeding populations are monitored, several tens to hundreds of chicks being ringed each year since 2006. This offers an opportunity for blood sampling in order to assess exposure to chemicals. Here, we present the results from a monitoring done on the Red kite in France during springtime 2013 and 2015. Blood was sampled from 121 chicks in 2013, metal(loid)s, rodenticides, PAHs and OCls were measured and related to body condition and breeding success. In 2015, analyses on different health indicators are currently in progress on 50 blood samples and results will be presented at the congress.

WE147

Emerging chemicals in birds of prey from Spain and Norway: exposure and effects

V. Jaspers, Norwegian University of Science & Technology / Biology; M.E. Løseth, N. Briels, Norwegian University of Science and Technology / Biology; I. Eulaers, Aarhus University DMU / Biosciences; C. Sonne, Aarhus University DMU / Biosciences Department; T. Nygard, J. Bustnes, Norwegian Institute for Nature Research; P. Gómez-Ramírez, University of Murcia / Sociosanitary Sciences; J. Martínez, University of Murcia; T. Johnsen, Norwegian Institute for Nature Research; G. Poma, University of Antwerp, Toxicological Center / Toxicological Center; G. Malarvannan, University of Antwerp / Toxicological Center Dept of Pharmaceutical Sciences; A. Covaci, University of Antwerp, Toxicological Center / Toxicological Center Dept of Pharmaceutical Sciences; D. Herzke, NILU - Norwegian Institute for Air Research / MILK

In 2014, the international research project NewRaptor was launched (funded by the Norwegian Research Council and the Norwegian University of Science and Technology). In this project, we investigate the exposure and effects of emerging chemicals in birds of prey from three regions (Murcia, southern Spain; Trøndelag, mid Norway; Troms, northern Norway). The goshawk (*Accipiter gentilis*) was studied in all three regions, while the marine white-tailed eagle (*Haliaeetus albicilla*) only in the two Norwegian locations. Both blood and body feathers were obtained from the chicks in the nest when they were 3-7 weeks old. The chemicals of interest include novel brominated flame retardants (nBFRs), organophosphate flame retardants (OPFRs) and per- and polyfluoroalkyl substances (PFASs). In addition, metals and legacy chemicals, i.e. persistent organic pollutants (POPs), were analysed as well. The objectives of the NewRaptor project are to evaluate the exposure of these two bird species to both emerging and legacy compounds in relation to habitat and dietary preferences (using stable isotope analysis), differences in latitude, and to evaluate the interactive effects of the pollutant mixtures on different biochemical, immunological and endocrine parameters. The first results of the sampling campaign in 2015 indicate that the PFAS exposure in goshawks from Murcia are lower than in Norwegian chicks, with up to 10 times higher values in Norway: e.g. linear PFOS < LOD-3.1 ng/ml in Murcia; 4.9-30 ng/ml in Trøndelag; 0.72-24 ng/ml in Troms). Regarding the white-tailed eagle, linear and branched PFOS were the most prominent PFAS (linPFOS: 6.0-32 ng/ml in Trøndelag;

WE148
Age-dependent changes in oxidative stress biomarkers and essential elements in blood of red deer
J. Pareja Carrera, J.A. Ortiz, IREC; R. Mateo, U.C.L.M.-C.S.I.C. / Instituto de Investigacion en Recursos Cinegeticos
Changes in the concentration of the essential elements in the blood of animals throughout their life may be indicative of periods of greatest vulnerability to deficiencies and associated diseases. Here we have studied the changes in antioxidant biomarkers and essential elements in the blood of females of farmed red deer along their life. These changes are discussed in relationship with the incidence of enzootic ataxia, white muscle disease and reproductive failure in farmed deer. Blood samples of female red deer (n=132) were analysed to determine the concentrations of essential elements with roles as cofactors in antioxidant enzymes (GPx and SOD). Moreover the activity of there antioxidant enzymes and antioxidant vitamins (retinol and α-tocopherol) was measured in the same blood samples. In addition, samples of plants, soil and water from the same study area were analysed to identify possible deficiencies and interactions of trace elements in the diet of the studied deer. Levels of Zn and Mn in blood decreased with age, whereas Se and Cu levels showed an increase during the first year of age and then stabilized at slightly lower levels the following years. Farmed deer showed deficiency levels of Cu during most of their life and, at a lesser extent, were also Se-deficient. The activity of GPX increased along the life of deer, while a decreasing trend was found for SOD. In the case of vitamins, retinol increased during the first year of age and tocopherol peaked at 3-4 years of age. Positive correlations were observed between the blood levels of Se and GPx activity and between levels of Zn/Cu/Mn and SOD activity. These results indicate that trace element deficiencies described above (especially Cu) may have an effect on the antioxidant capacity (especially SOD activity) of the animals at adult stages, when reproduction effort may increase antioxidant requirements. Cu deficiency in farmed deer could be related to low levels of Cu in soil of the study area or to elevated levels or sulphates in water that could lead to the formation of non-bioavailable forms of Cu in the digestive tract of deer. In summary, the use of enzymatic and non-enzymatic antioxidants as effect biomarkers of the exposure to pollutants should be always considered taking into account the age of the animals and the levels of essential elements acting as antioxidant cofactors.

An in silico modelling perspective to advance hazard assessment of aquatic ecotoxicology (P)

WE149
Linking algal growth inhibition to chemical activity: A tool for identifying excess toxicity
S.N. Schmidt, Technical University of Denmark / Department of Environmental Engineering; J.M. Armitage, University of Toronto - Scarborough / Physical and Environmental Sciences; J. Arnot, ARC Arnot Research & Consulting Inc.; K. Kusk, Technical University of Denmark; P. Mayer, Technical University of Denmark / Department of Environmental Engineering
Aquatic toxicity data are most often expressed on a concentration basis (e.g., EC50 in mg/L). Whereas the data are useful within regulatory risk assessment, a given EC50 value offers no direct information on whether the compound exerts baseline toxicity or excess toxicity. Chemical activity (a) is a medium-independent exposure parameter that quantifies the energetic level, and not the concentration, of an organic compound relative to its energetic level in pure liquid [0-1, unitless]. Several studies have linked toxicity to chemical activity, and baseline toxicity (narcosis) for neutral hydrophobic organic compounds has been shown to initiate in the narrow chemical activity range of 0.01 to 0.1. These findings suggest EC50 values for baseline toxicity to be at or above 1% of liquid saturation, and EC50 values well below this limit do thus indicate excess toxicity. In the present study, published toxicity data were expressed on a chemical activity basis in order to identify excess toxicity. More specifically, algal growth inhibition was linked to chemical activity using two approaches: (1) algal toxicity data were plotted relative to a regression for the (sub-cooled) liquid solubility, which served as a visual reference for chemical activity of unity and (2) ratios of algal EC50 values and (sub-cooled) liquid solubilities were determined, since the this ratio essentially equals the effective chemical activity (Ea50). In both approaches, compounds exerting toxicity well below the limit of 1% of liquid saturation (a=0.01) were identified as compounds exerting excess toxicity and investigated further. Also, the two approaches were compared on both a methodological and scientific level. In the present study, toxicity data came from several comprehensive and carefully conducted algal growth inhibition experiments covering a wide range of solid and liquid organic compounds, covering several expected modes of action and also several algal species. This presentation shows how the chemical activity concept can be used to compare and combine toxicity data across compounds and species in order to characterise toxicity – and further how the concept can be used in environmental risk assessment.

WE150
High-accuracy water solubility determination using log KOW from different methods
P. Bicherel, P. Thomas, KREATiS
Work was carried out to determine the relative accuracy of several experimental methods used to determine log K_{OW} values: HPLC (OECD 117); shake flask (OECD 107) and slow-stir (OECD 123). In order to do this log K_{OW} values were plotted against water solubility values. It was found that the method for log K_{OW} determination directly influenced the relationships found between log K_{OW} and water solubility. Water solubility is a parameter which is typically measured with a shake flask method (OECD 105) or improved using a slow-stirring method (derived from OECD 123 for log K_{OW} determination) when water solubility is low. When log K_{OW} data for a group of compounds (e.g. oxygenated substances excluding alcohols and acids) are divided between shake flask and slow-stir methods and compared to results from the HPLC method, goodness-of-fit of correlation are significantly different. Water solubility values correlate better with log K_{OW} values determined using shake flask or slow-stirring methods. However HPLC method overestimates log K_{OW} with an average error of 0.43 log units. HPLC cannot be used as a reliable method to measure log K_{OW} with accuracy and this is also the reason why HPLC data should be excluded as a data source during development of High-Accuracy QSAR models.

WE151
Analysis of sorption of non-ionic and anionic surfactants to different stationary phases
J. Hammer, University of Utrecht / IRAS; J. Haftka, P. Scherpenisse, J. Hermens, Utrecht University / Institute for Risk Assessment Sciences; P. de Voogt, University of Amsterdam / IBED
Anionic and non-ionic surfactants are high-production volume chemicals that are found in many consumer products and consequently also in the environment as organic contaminants. Octanol-water partition coefficients (K_{ow}) are often used in QSAR studies as a measure of hydrophobicity to predict the environmental fate and exposure of neutral organic compounds. However, K_{ow} is not meaningful for surface-active compounds because sorption to environmental matrices is not only driven by their hydrophobicity, but also by specific interactions with the sorbent (hydrogen-bonding and electrostatic interactions). Furthermore, experimental K_{ow} values of both non-ionic and anionic surfactants are difficult to determine because of their surface active properties and ability to emulsify the octanol-water system. Alternative approaches to quantify and predict the environmental behaviour of surfactants are therefore required. Our research is focused on developing and testing new approaches and parameters that can be applied in models to predict sorption and bioaccumulation of different surfactant classes. To this end we studied the interactions between surfactants and different stationary phases (C_{18}, Hydrophilic Interaction liquid chromatography (HILIC), and ion exchange) with a liquid chromatographic method. Retention times of surfactants were measured and capacity factors were extrapolated to 100% water (k'_0). The affinity of surfactants for the C_{18} phase increased with carbon chain length for both anionic and non-ionic surfactants. Fragment values (log D*k*) were calculated by multiple regression analysis of log k'_0 values for all surfactants. These values showed that hydrocarbon and fluorocarbon moieties contributed most to hydrophobicity while anionic head groups such as carboxylate, sulfonate, and sulfate groups contributed much less to hydrophobicity. All fragment values determined for the C_{18} phase could be interpreted through identification of interactions between surfactants and the aqueous phase (hydrogen-bond acceptors/donors, charged head groups) and are a good measure for the hydrophobicity of surfactants.Capacity factors for all stationary phases together may be applied as parameter in predictive models for sorption to specific environmental phases (e.g., membrane lipids or organic matter).

WE152
Reliability of BMD and ECx calculations required by Regulation EU 283/2013 for bird and mammal reproduction studies
M. Wang, WSC Scientific GmbH / Dept Efate   Modelling; M. Brauer, WSC Scientific GmbH; J. Hahne, Bayer CropScience AG; M. Ebeling, Bayer CropScience AG / Environmental Safety   Ecotoxicology
The ECx is a key endpoint for the long-term risk assessments of chemicals, including pesticides. Aquatic ecotoxicologists have since long argued in favor of using a defined point estimate (e.g. the EC_{10}) instead of the NOEC in longterm risk assessment. For avian and mammalian studies however, reliance has always been more on NOAELs as determined with statistical significance testing. Only recently EU regulation 283/2013 introduced the ECx in pesticide hazard identification and risk assessment, for all ecotoxicological areas, including birds and mammals. ECx endpoints are much better suited than NOAEL or LOAEL

also for combined assessments, e.g. in mixture toxicity evaluations, or for geometric mean calculations in case data are available from multiple studies or additional species testing. However, studies conducted, or evaluated, for bird and wild mammal longterm risk assessments are different from guideline studies in other ecotoxicological areas, with a comparatively high number of endpoints, but generated in test regimes with typically only three dose levels plus control. Therefore, ECx evaluation of such studies needs careful consideration. EU 283/2013 stresses the importance of reliable endpoints for risk assessment; this applies, of course, also to the calculation of ECx values. Currently, different approaches are used for calculation of ECx for bird and mammal studies, which are based on different principles and have a different historical background. Benchmark dose (BMD, equivalent to ECx) calculations are one of the newer approaches, developed for human toxicology and based on the precautionary principle. The key principle of BMDs is that different functions are compared and finally a conservative one is chosen to determine the BMD and its confidence intervals. In ecotoxicology, conventionally only a few (or even a single) dose-response functions are used and different methods are used to select the most adequate one. The selection of dose-response curves in ecotoxicology often follows other principles than the BMD approach. In the present study benefits and drawbacks of the calculation methods are compared and a new approach is proposed for calculation of robust and reliable ECx values. The proposed approach integrates the benefits of existing methods and provides endpoints that comply with the reliability criteria and is based on the OECD guidance for statistics in the analysis of ecotoxicity data.

WE153

A unique QSAR model to determine microorganism toxicity in activated sewage sludge

P. Thomas, J. Oses, P. Bicherel, KREATiS

Toxicity of microorganisms, usually following the Activated Sludge Respiration Inhibition Test (ASRIT) – OECD guideline 209 is a required endpoint in fulfilment of Annex VIII in REACH dossiers i.e. substances produced in quantities >10 TPA. Physicochemical properties (like adsorption to sludge or volatility) as well as the lack of obligation for analytical quantification makes it difficult to perform this test for some substances and interpretation can be ambiguous. In order to replace this kind of experimentation a High-Accuracy QSAR model has been developed. This work has been carried out as a part of the DAMIER project, a French funded project for the development and the use of High Accuracy QSAR models for REACH compliance. Therefore the model meets the five OECD principles (OECD, 2004) and has been validated to provide accurate EC50 values for non-polar narcotic substances. The algorithm is based on a simple linear relationship which links toxicity to activated sludge microorganisms to sub-cooled liquid solubility. It is based on the concept that chemical activity expressed through water solubility can explain aquatic toxicity as has previously been shown for fish, invertebrates and algae (Mackay *et al.*, 2009; Thomas *et al.*, 2015). This is the first model in ecotoxicity able to predict such an endpoint for regulation known to the authors.

Mechanistic effect modelling for risk assessment: state of the art, applications, use in a regulatory context and future directions (P)

WE154

A DEB analysis of responses to baseline toxicants in C. dubia and D. magna

B. Goussen, University of York / Environment Department; C. Rendal, E. Butler, J. Roberts, O. Price, A. Franco, Unilever / Safety and Environmental Assurance Centre SEAC; T. Gouin, Unilever / Safety and Environmental Assurance Centre; G. Hodges, Unilever / Safety and Environmental Assurance Centre SEAC; T. Jager, DEBtox Research / Dept of Theoretical Biology

Mechanistic effects models are gaining interest in the scientific community and in regulatory settings. These models have the potential to facilitate species extrapolation, thereby decreasing the need for toxicity testing for risk assessment. They also provide an opportunity to quantify the complexities of multiple interacting stressors on environmental scenarios. Dynamic energy budget (DEB) theory represents a unifying framework for assessing the mechanisms that drive toxicant effects on life history traits. We report here on the progress of two case studies for an example chemical tested on two species of Cladocerans, *Ceriodaphnia dubia* and *Daphnia magna*. Over 70% of the ingredients in home and personal care products are considered baseline toxicants. We use phenol as a model baseline toxicant. A dynamic energy budget model was calibrated for each species, and differences in parameters and physiological mode of action are discussed. This work also explores how DEB based modelling can incorporate environmental factors such as food availability and temperature into risk assessment. In conclusion, the present study demonstrates the potential utility of DEB based models for species extrapolation and chemical risk assessment in an AOP framework.

WE155

Calculation of exposure-specific species sensitivity distributions by toxicokinetic-toxicodynamic modelling for the insecticide compounds imidacloprid, chlorpyrifos, and lambda-cyhalothrin

D.M. Buijert-de Gelder, Wageningen University / Aquatic Ecology and Water Quality Management; A. Focks, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team; P. van den Brink, Alterra and Wageningen University / Aquatic Ecology and Water Quality Management Group

Species sensitivity distributions (SSDs) are statistical distributions describing the variation among a set of species sensitivity towards a certain compound or mixture. An SSD can be made by fitting a statistical distribution through the results of acute or chronic toxicity tests for several species. SSDs can be used in environmental risk assessment of chemicals in two different ways, either for defining Environmental Quality Criteria (EQC), such as the often used HC5 concentration that is thought to be protective for 95% of all species in a community, or to estimate the fraction of potential affected species (PAF). In this work, we used toxicokinetic-toxicodynamic (TK/TD) models that were already parameterised for the insecticide compounds imidacloprid, chlorpyrifos, and lambda-cyhalothrin to generate model-based toxicity values for a series of time-variable exposure scenarios. Exposures contained different time-variable exposures, or chronic exposures over prolonged times, up to 100 days. SSDs were then generated based on these toxicity values, and could be compared with experiment-based SSD. The aim of this study is to assess how protective SSDs based on acute toxicity experiments are in the light of environmentally relevant time-variable exposure concentrations. Model-based HC5 and HC50 values were compared with respective values from experiment-based SSDs for chlorpyrifos, and hardly any differences could be identified, hence the method can be considered to work. Current results indicate that only small differences in HC5 values for the investigated compounds are visible for the different exposure profiles. This depends on the TKTD characteristics of the chemical, the type of TK/TD model used and the length and type of the time-variable exposure regimes. Further results will investigate also HC50 values which are supposed to show larger differences.

WE156

Application of Toxicokinetic-Toxicodynamic Modelling of Effects of Chlorpyrifos-Methyl on the Survival of Aquatic Macroinvertebrates for Environmental Risk Assessment

A. Focks, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team; N.N. Poletika, Dow Agro Sciences LLC / Field Exposure and Effects Department; D.A. Yon, Dow Agrosciences; P. van den Brink, Alterra and Wageningen University / Aquatic Ecology and Water Quality Management Group

In this study, toxicokinetic/toxicodynamic (TK/TD) models were calibrated, validated, and used for predictions for analysing effects of chlorpyrifos-methyl (CPF-M) on the survival of the mayfly, *Cloeon dipterum*, the crustacean, *Gammarus pulex*, and the dipteran, *Chironomus riparius*. Model calibration was performed based on data from laboratory toxicity studies conducted with the three species and CPF-M, by fitting the model parameters to the data and calculating their confidence limits. The parameterised models were validated with independent data on the toxicity of chlorpyrifos (CPF), because there were no appropriate datasets for testing available for CPF-M. The calibrated and as far as possible validated model parameters were used to predict effects of concentration time series selected from 133 FOCUS Surface Water Step 4 exposure scenarios on the survival of the three macroinvertebrate species. The ultimate objective was to check that if CPF-M is applied according to the proposed application scenarios, then exposure only leads to negligible levels of individual mortality for the three sensitive macroinvertebrate species in edge-of-field water bodies. For *C. dipterum*, the least sensitive of the three investigated species, deterministic and probabilistic analyses indicated that more than the 10-fold of the predicted environmental concentrations would still only lead to negligible effects (mortality< 10%). For the second-most sensitive species, *G. pulex*, deterministic analyses indicated that for moderately increased concentration levels, i.e. up to the 4 fold of the predicted environmental exposure, non-negligible effects can be excluded. For the most sensitive species *C. riparius*, all analyses gave indications that predicted environmental concentration levels would lead to non-negligible effects on survival. It must be critically remarked, however, that as a result of model calibration overestimation of mortality is likely for concentrations larger than 0.2 μg/L, and that quality and quantity of validation data for *C.riparius* did not allow firm conclusions about the realism of predictions. Modelling results show the potential of screening large numbers of exposure scenarios using TK/TD modelling, and how TK/TD models can be used to evaluate realistic time-variable exposure more extensively than by toxicity-exposure ratios alone. The results show that the toxicity potential of an exposure scenario is not governed by the maximum concentration alone.

WE157

Quantification of uncertainty in toxicokinetic-toxicodynamic model predictions

A. Focks, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team; F. Gabsi, Rifcon GmbH; S. Reichenberger, DR. KNOELL CONSULT GmbH / FOOTWAYS SAS; N. Kramer, Utrecht University

/ Institute for Risk Assessment Sciences; N. Cedergreen, University of Copenhagen / Plant and Environmental Sciences; V. Ducrot, Bayer CropScience AG / Environmental Safety Ecotoxicology; R.B. Schaefer, University of Koblenz-Landau / Institute for Environmental Sciences; T. Jager, DEBtox Research / Dept of Theoretical Biology; R. Ashauer, University of York / Environment

Toxicokinetic-toxicodynamic (TK/TD) models quantify the expected chemically-induced mortality from any time-variable, environmentally relevant exposure profile (Ashauer et al., submitted), leading to more realistic predictions of individual and population level effects on sensitive species. The flexibility of TK/TD models enables their use for different extrapolation purposes of relevance in risk assessment. As an example the evaluation of potential toxic effects from the defined exposure time series in the FOCUS surface water models (Ashauer et al. 2013). TK/TD models allow directly relating exposure patterns to expected effects, thereby increasing accuracy and decreasing method-associated uncertainty of risk estimates. In addition, TKTD model predictions provide a means for quantifying uncertainty that is associated to biological variability as captured in the TK/TD model parameters. This study shows how information collected during model parameter estimation can be used to analyse uncertainty of model predictions in a probabilistic way. Model parameters were estimated from observed survival data for a set of four pesticides (carbendazim, cypermethrin, dimethoateand malathion), by maximizing the likelihood estimation. To approximate the joint confidence regions of all parameters, those parameter sets from the optimisation procedure that were not rejected in a likelihood ratio test were selected and subsequently used to generate forward predictions. The minimum and maximum of all predictions at each time point can be interpreted as a 95% uncertainty interval on the model predictions (reflecting parameter uncertainty). Model results for the four selected pesticides indicate that the sample size, the quality of data used for model calibration and the properties of the chemical-species interactions (e.g., the speed of the toxicokinetic and toxicodynamic recovery processes) have a direct impact on the parameter estimates, in particular uncertainties, and hence on the precision of model predictions as reflected by the size of the uncertainty bands of survival dynamics plots of and dose-response curves. Deterministic model predictions using best-fit parameters are in this way augmented with information about uncertainty of model predictions. This supports the evaluation of such model predictions for consideration in the regulatory environmental risk assessment of chemicals.

WE158

Variability in life stage sensitivity is a matter of toxicokinetics

A. Gergs, gaiac - Research Institute for Ecosystem Analysis and Assessment / Department of Environmental Social and Spatial Change; F. Gabsi, Rifcon GmbH; A. Zenker, University of Appl. Sc. Northwestern Switzerland / Institute of Ecopreneurship; T. Preuss, Bayer CropScience / Environmental Modelling

Aquatic effect assessment uses results from short-term laboratory experiments in which it is purposely attempted to keep constant exposure conditions and to minimize inter-individual variability, mainly in the body size or age of the tested animals. In contrast, natural populations are in most species size- or age-structured. Body size is an important demographic attribute, not only because it determines population properties such as abundance and density but also controls the main ecological processes regulating population dynamics such as density-dependence and size-selective predation. Furthermore, individuals in the same population exhibit different sensitivities to the same exposure conditions, depending on their life stage, which means that toxicity might be under or overestimated based on the standard toxicity tests. In this study, we investigated to what extent intraspecies variability in sensitivity can be explained by differential toxicokinetics, i.e. uptake and elimination of the chemical. Furthermore, we tested toxicokinetic-toxicodynamic models of different complexities, including body size scaling approaches, for their ability to represent lethal effects observed for *Daphnia magna* exposed to triphenyltin. To assess the consequences of these approaches at the population level, we simulated different scenarios using an individual-based model and confronted predictions with population data from pulsed exposure scenarios. Our aim is to evaluate the importance of considering population demography in toxicokinetics and toxicodynamics for understanding and predicting potential chemical impacts at higher levels of biological organization.

WE159

Ecological scenarios for the assessment of chemical effects on stream communities: a mechanistic modelling approach

A. Gergs, gaiac - Research Institute for Ecosystem Analysis and Assessment / Department of Environmental Social and Spatial Change; S. Classen, Research Institute gaiac; A. Palmqvist, Roskilde University / Department of Environmental Social and Spatial Change; T. Strauss, Research Institute gaiac / Research Institute Gaiac; M. Hammers-Wirtz, Research Institute gaiac

The ecological risk assessment of chemicals aims at quantifying the likelihood of adverse ecological effects posed on populations and the communities they comprise. Effects caused by the exposure of organisms to toxicants can however to a great extent depend on environmental scenarios as well on the states, behaviors and interactions of organisms with consequences for individual life history, population responses and community dynamics. In the past, these aspects have often been ignored in ecotoxicology and the calculation of adverse effect concentration, which classically focuses on toxicant concentration responses while keeping the environmental conditions as constant as possible. We present the conceptual design of a mechanistic simulation model which aims at the integration of environmental scenarios into the ecological risk assessment of chemicals. This individual based community model will integrate stream typologies as formulated within water framework directive, functional trait data bases, spatial explicit movement behavior, dynamic energy budgets triggering live history processes and toxicokinetic-toxicodynamic models linking exposure and effects in a dynamic manner. We anticipate that this project will increase the understanding of how chemicals act on multiple interacting species and provide a basis for bringing more ecological realism into the ecological risk assessment of chemicals.

WE160

Quantifying the energetic cost of toxicant stress in insects: a full cycle approach

J.L. Maino, University of Melbourne / School of Biosciences; A. Barsi, Board for the Authorisation of Plant Protection Products and Biocides; T. Jager, DEBtox Research / Dept of Theoretical Biology; A. Bednarska, Polish Academy of Sciences / Institute of Nature Conservation

The standard dynamic energy budget (DEB) model represents a quest for the simplest model that can describe the full life-cycle bioenergetics of all living organisms. Progress toward this goal is made by emphasising similarities between organisms, rather than differences. Such universal life processes include energy acquisition, growth, development, maintenance, excretion and reproduction. However, substantial modifications to this model are required to capture insects in a DEB context. These insects pose several challenges for ontogenetic development modelling, including discontinuous growth due to moulting, non-standard growth curves, lack of growth in adults, and the energetics of metamorphosis. Here we present a simple DEB model for insects that captures energy allocation processes through the egg, larval, pupal, and adult stages. The model is tested against both original and compiled data on growth, development, stoichiometry, respiration, and reproduction for a variety of insects and is shown to predict such data well. We demonstrate that toxic stress induces a range of measurable effects, from increased development time to increased respiration, that can be linked and quantified using our presented framework. Through the mechanistic modelling of fundamental energetic processes, the presented bioenergetics model for insects can be used to better quantify sub-lethal effects of toxic stress at the system level of the organism. The project was financed by the National Science Centre project HARMONIA (No. 2012/06/M/NZ4/00137).

WE161

DEVELOPMENT AND APPLICATION OF GENERIC TOXICOKINETIC MODELS IN FISH TO ENVIRONMENTAL RISK ASSESSMENT OF CHEMICALS

A. Grech, INERIS / Models for Ecotoxicology and Toxicology METO; N. Quignot, LASER; C. Brochot, INERIS / Models for Ecotoxicology and Toxicology METO; J. Dorne, European Food Safety Authority EFSA / Scientific Committee and Emerging Risks Unit Department of Risk Assessment; F. Bois, R. Beaudouin, INERIS / Models for Ecotoxicology and Toxicology METO

One of the goals of environmental risk assessment is to protect animal populations and the whole ecosystem from adverse effects resulting from exposure to single or multiple chemicals. In principle, risk assessment methodologies rely on combining estimates of exposure to the chemical(s) with toxicity data (hazard) used for risk characterisation. Exposure assessment aims to quantify “external dose”, as the amount of chemical agent(s) that reaches an organism. Hazard assessment for a chemical aims to quantify the relationship between dose and toxicity so that reference points can be set to derive environmental standards for specific protection goals. Over the last two decades, many research efforts have aimed to improve the quantification of such dose response relationships through the integration of “external dose” and “internal dose” namely toxicokinetic (TK)/ADME (Absorption, Distribution, Metabolism, and Excretion) processes. For this purpose, TK models have been developed to estimate internal doses from external doses in a time dependent manner, characterise the consequence of metabolism to identify the toxic species for a given compound (parent compound/metabolite) as well as extrapolate between laboratory and environmental conditions or between species. The purpose of this project is to develop a generic TK model for fish species to predict internal doses under different environmental scenarios of exposure. The model will be adaptable to a number of teleost fish species and validated by using data for studies on regulated products (*e.g*. pesticides) and environmental contaminants. Extensive literature searches will be performed to review models and tools incorporating TK for environmental risk assessment, collect biological and physiological parameters for given fish species and TK parameters for chemicals of environmental relevance. From this data collection exercise, tools aiming at predicting TK parameters for a number of fish species (*i.e*. interspecies extrapolation) will be developed. These tools will allow the calibration of fish physiologically-based TK (PB-TK) model taking into account several compartments (*e.g*. liver, fat) to model ADME processes for chemicals under different exposure scenarios. Finally, the predictive ability of the model and the uncertainties will be assessed for both TK parameters taking into account fish species differences and prediction of toxicity parameters.

WE162

Using mechanistic effect modelling to justify the TWA approach in aquatic risk assessment

T. Preuss, Bayer CropScience / Environmental Modelling; A. Solga, Bayer CropScience AG; V. Ducrot, Bayer CropScience AG / Environmental Safety Ecotoxicology; G. Goerlitz, Bayer CropScience AG / Environmental Safety; E. Bruns, Bayer CropScience AG / BCS D ETX Ecotoxicology

Risk assessments based on laboratory toxicity tests performed under constant exposure conditions may overestimate potential risks if the exposure concentration of the experiment is compared the PEC_{max} for short term exposure situation. To use PEC_{TWA} for the aquatic risk assessment several criteria have to be assessed following the EFSA Aquatic Guidance document: reciprocity and onset of effects as well as latency of effects. Most of these criteria cannot be assessed based on standard studies alone. On the one hand several endpoints are only measured at the end of the experiment. On the other hand effects are often found only in a few concentrations. Therefore mechanistic effect modelling especially toxikokinetics-toxicodynamics modelling is already recommended in the EFSA Aquatic Guidance document to test these questions. In this poster we will demonstrate case studies in which we used mechanistic effect modelling (namely GUTS and IDamP) to justify the TWA approach compound and species specific. Therefore the models were calibrated to the experiment triggering the risk assessment, if possible the preditive power of the models were tested on a different dataset (model validation). In the last step the models were used to investigate the questions necessary to justify the TWA approach according to the EFSA Aquatic guidance document.

WE163

Landscape context in bee risk assessment - a way to a realistic worst case environmental scenario

T. Preuss, Bayer CropScience / Environmental Modelling; A. Jeltzsch, University of Potsdam; M. Miles, Bayer CropScience UK / Environmental Safety; T. Schad, Bayer CropScience / Environmental Modelling

The western honey bee (*Apis mellifera*) is considered one of the most important pollinators concerning food crops. No sole underlying cause for increasing winter colony loss has been found so far, although there is consensus that the issue is of multifcatorial nature, and that multiple stressors, in addition to pesticides especialy landscape characterisitics and parasites play an important role. In the present work a modified version of the BEEHAVE model has been used to understand the effects of pesticides on a single beehive under different ecological conditions. A pesticide module was added to simulate the effects of pesticides on foragers and larvae due to nectar and contact exposure. Virtual experiments are conducted to figure out how landscape context, weather, beekeeper practice and *Varroa* mites affect the outcome of a pesticide risk assessment. Virtual experiments were conducted on different levels of complexity starting with two artifical patches over simplified scenarios up to realistic landscapes. The model approach allows to adress directly the specific protection goals, namely colony survival, colony size (number of bees in a colony) and honey production. We tested in virtual experiments different combinations of beekeeping practice, weather and landscape features on bee colony health with and without the impact of a hypothetical pesticide. This kind of analysis could not be conducted experimentally showing the strength of simulation models like BEEHAVE for environmental risk assessment. As defined in the EFSA Scientific Opinion on Good modelling an environmental scenario is a combination of agronomic, abiotic and biotic parameters which forms a realistic worst case situation. We will demonstrate that if setting up ecological scenarios the baseline against which the pesticide is tested has to be clear and this is not straightforward. To exclude unrealistic scenarios we suggest introducing the following constraint (boundary condition) for a realistic worst case scenario for bee risk assessment: honey harvest of at least 20 kg per hive should be possible within each year otherwise the beekeeper would not place their colonies in this landscape Comparison of simple scenarios with realistic landscapes shows that realistic scenario selection can be possible, but a minimal complexity is necessary for an realistic worst case environmental scenario.

WE164

Colony level impact of sublethal pesticide effects on honeybees: a simulation study using BEEHAVE

P. Thorbek, Syngenta / Environmetal Safety; P. Campbell, Syngenta / Environmental Safety; H. Thompson, Syngenta Ltd / Environmental Safety

The research on neonicotinoids and honeybees have changed focus from direct mortality to sublethal effects such as reduced mobility, learning, orientation and effects on brood care. Most of these tests have been performed in the lab using methods such as the proboscis extension reflex or histology, which would be challenging to translate into quantifiable effects on the individual's or colony's performance under field conditions. Here we use a published honeybee model, BEEHAVE [1], to study what impact sublethal effects may have on colonies. We combined two crop scenarios (oilseed rape, sunflower) with direct mortality and three sublethal effects (brood care, disorientation, flower handling). Actual effects on individual bees will depend on exposure concentrations, but our purpose was to compare responses so we enforced effect sizes that caused colony level impact. In the oilseed rape scenarios, poor brood care had the largest colony impact as it created a bottleneck for the important spring build-up of the workforce. For all effect types, the impact on number of workers typically peaked about a month after exposure and lasted some time before the colony started to recover. In the sunflower scenarios, the exposure timing was later and that changed the colony's response to the toxic effects. The colony impact now peaked during exposure and the ranking of effects differed with poor brood care now having negligible impact, because the reproductive season was ending. In contrast effects on foragers were more severe because the bottleneck now was build-up of honey stores. In both crop scenarios, good forage mitigated all effect types substantially. We recommend that in field studies colony assessments should continue at least one month after exposure finishes in order to ensure detection of ecologically relevant sublethal effects. Our results indicate, that even if the actual sublethal effect is difficult to detect in the field, subsequent ecologically relevant impact on colony dynamics would be clear if colony assessments are continued and/or if the colony is placed on scales. While sublethal effects may have the potential to impact colonies, evidence from several published field studies indicates that the exposure following seed treatments is not sufficiently high to induce such ecologically relevant effects because no colony level impacts are seen. 1] Becher et al. 2014. *J Appl Ecol* 51:470-482.

WE165

Modelling the effect of bioturbation on pesticide exposure of benthic Chironomus riparius populations

L. Wipfler, H. Bergstedt, Alterra Wageningen UR; H. Baveco, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team; W. Beltman, Alterra Wageningen UR; A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group

Hydrophobic pesticides accumulate in sediments and may pose a risk to benthic organisms. Benthic organisms are exposed via pore water and ingestion of contaminated organic matter. The vertical distribution of pesticide in the sediment determines to a large extent the relative importance of both exposure routes, driven by diffusion in pore water, degradation, adsorption and bioturbation. Bioturbation is associated with considerable increase in the vertical transport due to bioactivity but is currently not considered in the EU pesticide risk assessment. The objective of this research is to assess the impact of bioturbation on the survival of a benthic organism, while using a modelling approach. Diepens et al. (submitted) calculated exposure profiles in the upper 1 cm of the sediment (pore water) and the upper feeding layer of 0.2 cm of the sediment (in organic matter, OM) after pulsed chlorpyrifos entries following a standard FOCUS pond scenario. These profiles were linked to a *C. riparius* population model, with individual exposure linked to effects by means of a toxico-kinetics toxico-dynamics (TKTD) model. In this study similar concentration profiles were calculated while including bioturbation as a particle dispersion process in the TOXSWA model. Comparison of chlorpyrifos exposure profiles with and without bioturbation showed that the profiles of pore water concentrations did not deviate much, however, OM bound concentrations were lower in the top 2 mm when bioturbation was considered. The impact on *C. riparius* population exposure was also less than when neglecting bioturbation. Hence making the risk assessment more realistic by taking into account bioturbation of sediment-bound chemicals may change the outcome considerably. A next step will be to include possible feedback mechanisms between population density and bioturbation. *References* Diepens, N.J., J.M. Baveco, W.H.J. Beltman, A.A. Koelmans, P.J. Van den Brink. Dynamics and recovery of a sediment exposed *Chironomus riparius* population: A modelling approach. (submitted)

Individual-based simulation models of multi-species systems under the impact of chemicals: Complex dynamics can lead to changes in population recovery times and regime shifts

H. Baveco, A. Focks, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team; F. De Laender, Université de Namur ASBL / Laboratory of Environmental Ecosystem Ecology; P. van den Brink, Alterra and Wageningen University / Aquatic Ecology and Water Quality Management Group

There is a tendency to include ever more realism in models used for prospective environmental risk-assessment. Incorporating species interactions in multi-species models, may lead to emergent 'complex' dynamics and systems with alternative stable states (ASS). With ASS sudden shifts to alternative state may occur, following disturbances. In a previous study, we analysed complex dynamics in individual-based models (IBMs), combining IBM simulations with analyses of a strategic model. We found that stress could change the stability regime of multi-species models and trigger transitions to ASS. As an example of competing species the aquatic macro-invertebrates *Asellus aquaticus* and *Gammarus pulex* were chosen; the classical Lotka-Volterra competition model (LVCM) served as the accompanying simple, mathematically-tractable, model. Identifying the potential of ASS in multi-species systems emerged as one of the important roles of models. With the same models, we perform additional analyses aimed at further understanding the consequences for risk assessment. Firstly, we identify what might go wrong with estimates of recovery times when these are based on a single-species models, when in the actual, real, system, competitive interactions occur. Secondly, we show how much of the rich behaviour of the system we would 'miss', when we address competition but a-priori limit ourselves to the region in parameter space associated with coexistence. Results show that an observer of the dynamics of *Asellus* only, will encounter a bewildering variety of behaviour, ranging from fast and slow recovery to quick extinction. This variety in dynamics is logically related to the settings chosen for the competitor and easily explained from bifurcation diagrams. We conclude that when competition is playing a role, it needs to be addressed in population models, as it will have a large impact on recovery times. Recovery times depend on characteristics of target and competitor species. When the multi-species system has ASS, this is an additional complicating factor: the relative abundance after a stress event may lead to a regime shift, implying that recovery of the target species will never take place. Considering dynamics only for the coexistence case will ignore an important part of the potential behaviour of a competition system, and thus many possible alternative outcomes for recovery times will not be accounted for. From the results, we formulate a set of recommendations.

WE167
CPFISH: A new approach for evaluation of binary data in many-to-one control vs. treatment setups
R. Lehmann, FOM Hochschule für Oekonomie & Management University of Applied Science / FOM Hochschule für Oekonomie   Management; J. Bachmann, B. Karaoglan, J. Lacker, German Environment Agency; C. Polleichtner, German Environment Agency (UBA) / Ecotoxicological Laboratory; H. Ratte, ToxRat Solutions GmbH / Institute for Environmental Research; M. Ratte, ToxRat Solutions GmbH
Fisher's exact test for pairwise comparisons of proportions is widespread. However, sequential application induces alpha inflation. Bonferroni correction or Bonferroni-Holm correction of p-values are often used to overcome this issue. For detection of significant effects in binary control vs. treatment setups proportion data are often evaluated by using multiple statistical tests, e.g. Dunnett t-test. While normal approximation of these data is a minor problem multiple t-tests suffer from variance heterogeneity. Applying arcsin-square root transformation variance homogeneity is provided. However, normal approximation is corrupted. To avoid data transformations the Cochran-Armitage-test has been proposed to investigate trends in proportions. The test statistic used is approximately normal. Thus, critical values, p-values and derived significant effects lack of statistical accurateness, too. Other tests based on approximate normal distribution are the maximin efficiency robust test, MAX3, the constrained likelihood ratio test and the GMS. In times of high computational power we can account for alpha inflation by using the closure principle (CP), instead. There is no need for adjustment of p-values. We propose to apply the extended version of Fisher's exact test (FISH) for 2 x c contingency tables in coherence with the CP using R statistic software. The FISH neither makes use of data transformations nor of approximate distributions. Using the real binomial distribution of the data CPFISH does not suffer from the drawbacks induced by normal approximation and heterogeneous variances. By combining CP and FISH the CPFISH is derived. The applicability of CPFISH is shown by means of real and fictitious data sets. Finally, we compare CPFISH to the well-established approaches of Dunnett's multiple t-test in coherence with arcsin-square root transformation and Fisher's exact test in coherence with adjusted p-values using Bonferroni and Bonferroni-Holm correction.

WE168
Species Sensitivity Distributions with Censored Values
J.W. Green, DuPont / Applied Statistics Group
Species Sensitivity Distributions (SSDs) are increasingly requested by regulatory authorities, especially in the EU, as part of product registration submissions. There is some inconsistency among country regulators and EFSA guidance as to requirements and acceptable methods of fitting and interpreting SSDs. The primary issue to be discussed the handling of censored values (e.g., EC50>100 ppm). It has become common in some EU registrations to reject species data for SSD purposes if the data do not conform to the log-normal distribution. There is no scientific basis for this requirement and its use does not serve regulatory conservatism. Indeed, exclusion or improper treatment of censored values tends to increase HC5 estimates. Another issue is forcing all data to fit a single distribution, such as log-normal. It is shown that this too can produce significant bias. The treatment of censored data in SSD fitting has not received as much attention as it deserves, given that right-censored data is common in toxicity studies and occasionally, left-censored values are found. The later are common in monitoring data, but not common in toxicity studies. Some recent regulatory guidance suggests discarding censored values in fitting an SSD. (e.g., EFSA 2014; EFSA 2015; Schmitz *et al*. 2015) or using them only under strict conditions (EFSAS 2013). There is no scientific basis for avoiding censored values or for treating them as uncensored. There have long been known mathematically correct ways to include censored values in fitting a distribution. Ignoring censored values means the distribution being analyzed is truncated and there are well known differences between truncated log-normal and log-normal distributions. The bias introduced by eliminating censored values will be demonstrated, both through datasets used in product registrations, computer simulations, and mathematics. A well-known mathematically correct approach to including censored values will be described. Force fitting a standard distribution or rejecting data that do not conform to this distribution, and exclusion or improper treatment of censored data will bias the HC5 and HC5LB estimates. Mathematically sound and tractable methods for selecting distributions and handling censored values are known and available in validated software. There is no good reason for ignoring sound science in fitting or interpreting SSDs.

WE169
Dynamics and recovery of a sediment exposed Chironomus riparius population: A modelling approach
N. Diepens, Wageningen University; W. Beltman, Alterra Wageningen UR; A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group; P. van den Brink, Alterra and Wageningen University / Aquatic Ecology and Water Quality Management Group; H. Baveco, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team
To assess risks of sediment-bound contaminants, larger temporal and spatial scales have to be addressed than can be covered in laboratory tests. Although models can address these scales, they usually lack the coupling between chemical fate in the sediment, toxicokinetic-toxicodynamic processes in individuals and the propagation of individual-level effects to the population. We developed a population model that includes all these processes and assesses the importance of chemical uptake routes on damage and recovery of a *Chironomus riparius* population after pulsed chlorpyrifos exposure. We show that particle ingestion is an important additional exposure pathway affecting *C. riparius* population dynamics and recovery. Neglect of particle ingestion underestimates damage and recovery times, which implies that risks of sediment-bound chemicals are underestimated. Additional scenario studies showed the importance of selecting the biologically relevant sediment layer and the use of long term data output.

WE170
An individual-based model of the three-spined stickleback: incorporating effects on breeding behaviour into the assessment of endocrine disrupting chemicals.
K. Mintram, University of Exeter / Biosciences; P. Thorbek, Syngenta / Environmetal Safety; S.K. Maynard, Syngenta / Environmental Safety; A. Brown, Exeter University / Biosciences; C. Tyler, Biosciences College of Life and Environmental Sciences
Population modelling is employed to extrapolate from individual effects (including behavioural effects) to population-level effects in the environmental risk assessment (ERA) of chemicals. Population models that incorporate ecological processes such as density dependent competition, individual variability and aspects of behaviour would add further realism to risk assessment. Reproduction in some fish species involves complex breeding behaviours that can be affected by chemical exposure but ERA does not incorporate aspects of behaviour into regulatory testing. In the three-spined stickleback (*Gasterosteus aculeatus*) it has been shown that nest building, courtship displays and parental care, may be disrupted by exposure to endocrine disrupting chemicals (EDCs), consequently affecting population recruitment. Here, we present an individual-based model (IBM) for the three-spined stickleback with the purpose to simulate realistic scenarios for the chronic exposure effects of EDCs. The three spined stickleback is widespread geographically, and potentially sensitive to chronic exposure to EDCs that mimic sex hormones given its complex breeding strategy, low fecundity and the provision of high level of parental care. Density dependent growth and mortality and individual breeding behaviours are key parameters within the model. The IBM has been structured using a series of sub-models, based on empirical data obtained from published literature. The poster will present a full description of the model with some preliminary testing, and illustrate its potential application within ERA.

WE171
Tribolium castaneum under toxic stress: mechanistic effect model for a holometabolous insect
A. Barsi, Ctgb / Dept of Theoretical Biology; J.L. Maino, University of Melbourne / School of Biosciences; T. Jager, DEBtox Research; A. Bednarska, Polish Academy of Sciences / Institute of Nature Conservation
Various bioenergetics models for animal species are available to address questions about organism functioning under stressed conditions. However, a limited number of such models exists for holometabolous insects, mainly due to difficulties in capturing the complexity of their life cycle. These organisms are characterized by several metabolically distinct developmental stages, *i.e*. egg, larva, pupa and adult. We have developed a bioenergetics model to describe the entire life cycle of the red flour beetle *Tribolium castaneum* (Coleoptera: Tenebrionidae) under toxic stress. Experiments in which individuals were exposed to copper concentrations over 90 days were conducted. The obtained experimental data on individual

survival, growth, development and reproduction over time were used to calibrate the model. The model shows good performance at describing the life cycle of an individual organism. Although the beetles undergo a complex developmental path, our model captures well the pattern of toxic effects such as impaired development or reproduction. We demonstrate how conducting one integrative analysis, based on combined modelling and experimental approaches, may provide a valuable mechanistic insight into the energy budget of the red flour beetle under toxic stress. Finally, aiming at being generic for holometabolous insects, this model has a potential to address issues relevant for chemical risk assessment of regulatory important organisms such as bees or non-target arthropods. The project was financed by the National Science Centre project HARMONIA (No. 2012/06/M/NZ4/00137).

How representative are rat liver cytochrome P450s for possible endocrine disruptors identification? An in vitro azoles screening study.

E. Apazoglou, University of Coepnhagen / Plant and Environmental Sciences; N. Cedergreen, M. Gottardi, University of Copenhagen / Plant and Environmental Sciences

Endocrine disruptors are a group of chemicals that interfere with the endocrine system and are an emerging health concern. In this study we focus on the endocrine disrupting chemicals that inhibit the enzyme aromatase (CYP19) in the steroidogenesis and therefore create imbalance in the vertebrates' hormone systems. CYP19 belongs to a larger group of enzymes called cytochrome P450 monooxygenases, which are preserved across different species. They are heme-containing metalloenzymes that catalyze hydroxylation and oxidation on the metabolism of thousands of endogenous and exogenous compounds. Azole antifungal agents are designed to inhibit 14α-demethylase in the fungal ergosterol biosynthesis and therefore they act as inhibitors for other non-target cytochromes as well. In this study, 21 different azoles were tested *in vitro* on rat liver microsomes (ECOD) activity and compared with previous studies on CYP19, in terms of their inhibition potential. The rat liver microsomes were used to represent the cytochrome P450s enzymes and. There was a positive correlation (imidazoles a=0.34, R^2= 0.70 and triazoles a=0.68, R^2=0.52) between P450s and CYP19 50% inhibitory concentrations (IC50) suggesting that azoles were stronger inhibitors of P450s as compared to CYP19. Imidazoles appeared to be more potent than triazoles for both P450 and CYP19 inhibition. The structure and the lipophilicity of the compound play an important role for the affinity of the inhibitor for the enzymatic binding pocket. It was shown that inhibition, measured as IC50, increased with increased lipophilicity of the compound. For measuring P450 activity 7-ethoxycoumarin was used as a standard substrate because of its low selectivity. Testing different substrates such as testosterone can possibly be more relevant to compare to CYP19 activity. The results of this study are encouraging on further studying the possibility to use rat liver microsomes as representative for human CYP19 and as a screening tool for possible endocrine disruptors.

WE173

Critical Membrane Concentrations of Amines in In Vitro and In Vivo Fish Bioassays

s. droge, Utrecht University / IRAS; J. Hermens, N. Kramer, Utrecht University / Institute for Risk Assessment Sciences

Neutral organic contaminants are assumed to be nonspecifically toxic at the baseline critical membrane burden (CMB) of ~100 mmol/kg lipid. Assuming a contaminant's octanol-water partition coefficient (logP) is equal to its membrane affinity (logKmw), the specificity of the toxic mode of action (or 'excess toxicity') can be estimated, where CMB in mmol/kg lipid = median lethal concentration (LC_{50}) in mmol/L x logKmw in L/kg lipids. This assumption needs to be refined for contaminants that are predominantly present in their ionic form in toxicity assays as the CMB has only been determined for a large set of neutral contaminants. This is an important data gap in environmental risk assessment because the majority of pharmaceuticals and a substantial fraction of industrial chemicals are highly ionizable. The aim of this study was two fold: 1) to define the CMB for strong bases (pKa>9) using existing *in vivo* fish acute toxicity data from the US EPA Fathead Minnow Database, and 2) to determine whether this definition could be replicated in an *in vitro* cytotoxicity assay with a fish gill cell line (RTgill-W1). Membrane affinities for a series of amines listed in the US EPA's Fathead Minnow Acute Toxicity Database were determined using immobilized artificial membrane chromatography (IAM-HPLC), which allows for a direct interpretation of the critical membrane burden (CMB) in acutely exposed fish for these cationic chemicals. Accordingly, the CMB of thirteen amines with an unsure mode of action (MoA) was found to be within a very narrow range of 7.6±5 mmol/kg lipid, more than an order of magnitude lower than the baseline CMB for neutral chemicals. For the neurotoxic amines, the CMB of amphetamine was similar to those of the "unsure MoA" amines, while strychnine and nicotine showed an "excess amine toxicity" of a factor of 10, with CMB's of 0.6 mmol/kg lipid. RTgill-W1 cells were exposed for 48h to the abovementioned amines and cytotoxicity was assessed using the Alamar Blue assay. Test media were sampled before and after exposure and amine concentrations were analytically measured to define actual exposure concentrations. Unlike for neutral organic chemicals, *in vitro* median effect concentrations (EC_{50}) for the tested amines were at least twofold higher than fish acute LC_{50} values. This suggests that the specific mechanisms by which amines accumulate or cause toxicity *in vivo* are not replicated *in vitro*.

Application of a coordinated OMICS research program and data into regulatory frameworks: case-studies and perspectives (P)

WE174

Developing an enhanced experimental work-flow for maximising the use of 'omics data within the Adverse Outcome Pathway framework

N. Taylor, University of Birmingham / Biosciences; S. Schade, Birmingham University / Biosciences College of Life and Environmental Sciences; E. Butler, Unilever / Safety and Environmental Assurance Centre SEAC; S. Gutsell, Unilever / SEAC; J. Zhou, N. Shi, S. He, University of Birmingham / Computer Science; K.G. Sappington, U.S. EPA / Office of Pesticide Programs; A. Biales, U.S. EPA / National Exposure Research Laboratory; G.T. Ankley, U.S. EPA / National Health and Environmental Effects Research Laboratory; J. Colbourne, University of Birmingham / Biosciences College of Life and Environmental Sciences; M.R. Viant, University of Birmingham / School of Biosciences; G. Hodges, Unilever Research / Safety and Environmental Assurance Centre

Developments in 'omics technologies have opened new possibilities for assessing the molecular and biochemical responses of organisms to chemicals. Feature selection tools are increasingly being used to discover responses within the 'omics datasets that may be predictive of adverse outcomes. These molecular responses can help to define the "key events" (KEs) underpinning the toxicity pathway within an Adverse Outcome Pathway (AOP) framework. KEs are deviations from a healthy state, through a stress response, that may predict an adverse outcome and therefore indicative of a chemical's potential health hazards. Here we investigate the potential of multi-omics technologies to discover KEs of specific acting chemicals and baseline narcotics. The first phase of this work has been the development of a proposed work-flow of how to utilise the non-targeted, information rich, data attainable from omics investigations; incorporating this into an enhanced AOP driven risk assessment approach. The second phase has been to start to develop comparative multi-omics approaches as part of an integrated (weight of evidence) approach in combination with available *in silico* or *in vitro* data to support the categorisation of chemicals by their KEs based upon their molecular and biochemical responses in *Daphnia* and algae. We aim to achieve this by elucidating the relevant KEs of specifically acting chemicals and baseline narcotics and measuring the strength of the association with the subsequent adverse outcome. The use of organisms that span two trophic levels could enable qualitative assessment of the predictive capability of the KE(s) both within and across species, improving toxicity predictions for untested species and in setting exposure thresholds in environmental risk assessment. To identify target homology and further enhance cross species applicability, molecular target sequence analysis tools; such as the US-EPA developed SeqAPASS (Sequence Alignment to Predict Across-Species Susceptibility), will be utilised. Sampling at high temporal resolution (spanning the acute and chronic experimental stages) for the 'omics assays will provide reproducible toxicological effects measurable by gene expression and metabolite profiling. By detecting the point of departure from a healthy state, we aim to use acute exposure scenarios to predict chronic outcomes, ultimately streamlining the experimental design to capture just the KEs making the work flow rapid and cost-effective.

WE175

Transcriptome network analysis of toxicity pathways in aquatic organisms

D. Coman Schmid, Eawag Swiss Federal Institute of Aquatic Science and Technology; S. Pillai, Eawag Swiss Federal Institute of Aquatics; K. Schirmer, Eawag / Environmental Toxicology; A. Zupanic, Eawag Swiss Federal Institute of Aquatic Science and Technology / Environmental Toxicology

Network analysis is based on the guilt-by-association principle and it is a powerful method for identifying patterns within many types of data (e.g. social, medical, biological, environmental etc.). Aiming to expand our understanding of toxicity pathways in aquatic organisms, we developed *neτoxi* – an integrative systems biology workflow, which infers mutual information co-expression networks from large collections of transcriptome data in several organisms (e.g. green algae, zebrafish). Although the biological processes for some chemical stressors have been characterized, most toxicity pathways and their mechanisms of action at the cellular level are still unknown. Integrative bioinformatics and statistical analyses of large and diverse collections of omics datasets have great potential in revealing the mechanisms of cellular response of aquatic organisms to chemical stressors. Specifically, gene co-expression network analyses can identify hubs and modules of genes with similar expression patterns, indicative for structured, modular toxicity response characteristic to certain chemical stressors. *neτoxi* uses both in-house generated omics datasets as well as publicly available data, summing up to more than 650 transcriptome samples in *Clamydomonas reinhardtii*. An entropy based mutual information metric is then used to infer statistically significant co-expression relationships between gene products (i.e. transcripts). The resulting network is visualized as a graph (nodes represent genes and edges show co-expression relationships between genes) and various network statistics are employed to identify interesting patterns such as hub genes (frequently essential genes) and highly interconnected modules (indicators for groups of genes involved in the same cellular process and/or metabolic pathway). Our vision is to use *neτoxi* to identify models of toxicity pathways responses and to advance from single mechanism of action to toxicity pathway-based understanding of chemical effects on the transcriptome of aquatic organisms.

WE176

Ecological case studies using chemical, target and outcome-based approaches to AOP development.

K.A. Fay, University of Minnesota - Duluth / Biology; G.T. Ankley, U.S. EPA / National Health and Environmental Effects Research Laboratory; C. LaLone, U.S. EPA / Mid Continent Ecology Division; Y. Song, Norwegian Institute for Water Research NIVA; K. Tollefsen, NIVA; D.L. Villeneuve, U.S. EPA / Mid Continent Ecology Division

While formal guidance documentation exists for describing Adverse Outcome Pathways (AOP), development strategies are lacking. Here, different approaches for developing AOPs are considered, including: chemical-, target-, and outcome-based. The chemical-based approach to AOP construction is common. Often, a chemical with a well-studied mode of action is used to identify key events and propose relevant adverse outcomes. An example from the AOP knowledgebase (aopkb.org) is AOP 4: Ecdysone receptor (EcR) activation leading to mortality in Daphnia magna, which is based on the action of the EcR agonists 20-hydroxyecdysone, ponasterone A, and tebufenozide. Prioritization efforts can also drive chemical-based AOP approaches. For example, an AOP describing potential fluoxetine effects on aquatic species was developed because this anti-depressant commonly occurs in aquatic environments. For this effort, the U.S. EPA ECOTOXicology database, which captures single chemical toxicity data, was queried for the most sensitive endpoint (movement) and species (bivalves) to inform AOP 97: 5-hydroxytryptamine transporter inhibition leading to increased predation. Alternatively, target-based approaches to AOP development are widely used for the ongoing OECD effort to catalogue AOPs "that will enhance the utility of US EPA ToxCast high throughput screening data for hazard identification," including AOP 95:ERG channel inhibition leading to reduced survival. This AOP was developed considering a ToxCast assay which measures the inhibition of the ERG potassium channel, an ion channel essential for cardiomyocyte repolarization. After literature review of adverse effects from ERG inhibition, and analysis of protein target conservation across species, an AOP for effects in fish was constructed. Finally, examples of outcome-based approaches for developing AOPs are scant, although they frequently offer stronger weight of evidence for effects at the individual, population and ecosystem levels. For example, AOP 138: PAH channel inhibition leading to mortality, was developed largely from a single study that described dramatic declines in vulture populations. This study linked observations of renal failure and visceral gout in vultures to diclofenac exposure upon scavenging treated livestock. Subsequent studies provided additional information for early key events, including the ability of diclofenac to inhibit uric acid transport by the p-amino-hippuric (PAH) acid channel.

WE177

Environmental effects of cyanobacterial blooms on fish: a Metabolomic approach from experimental fish to natural population.

B. Sotton, MNHN / UMR Molécules de communication et adaptation des microorganismes; A. Paris, A. Blond, MNHN; G. Lacroix, ENS; A. Millot, CEREEP Ecotron IDF; S. Le Manach, MNHN; H. Huet, ENVA; B. Marie, MNHN / UMR Molécules de communication et adaptation des microorganismes

Due to the interactive effects of the eutrophication of aquatic ecosystems and global warming, toxic cyanobacterial blooms have become a major scientific concern. They are responsible of the production of a wide variety of toxic secondary metabolites implicated in various impacts on the stability and the functioning of aquatic ecosystems. The Microcystins (MCs) and more generally toxic cyanobacterial metabolites have been implicated in various negative effects experimentally induced on various fish species.\nRecently, with the development of "Omic" sciences, proteomic and metabolomics analyses, using nuclear magnetic resonance (NMR) and/or mass spectrometry (MS), have been shown to provide a powerful tool for the discrimination of metabolic responses between organisms exposed to different treatments and for the identification of metabolic pathways involved in toxicological mechanisms of various toxic compounds. However to our knowledge, there are no such investigations dealing with the global metabolic effects of toxic cyanobacterial blooms on fish using metabolomics analysis.\nIn this way, liver metabolome profiles were analyzed on four typical fish species of freshwater European lakes (perch, roach, crucian carp and pumpkinseed sunfish) exposed or not to cyanobacterial blooms, and originating from both field enclosures, mesocome experiments and field sampling. The aims of this study are (1) to investigate and identify the metabolic changes which may be observed in the different fish species according the presence of cyanobacterial blooms; (2) to assess and identify the potential different responses of the different fish species metabolomes under stress conditions due to a cyanobacterial exposition. These results originating from multi-approach observations will help us to better understand the genuine ecotoxicological effects of cyanobacterial blooms producing a wide variety of potential noxious metabolites on fish populations from natural ecosystems.

WE178

Use of the fresh mussel Dreissena complex as a tool for ecotoxicological studies: development of genomic tools

A. Tanguy, UPMC; E. David, Université de Reims Champagne Ardenne / UFR Sciences Exactes et Naturelles; M. Auffret, Universite de Bretagne Occidentale / LEMAR

Various species of aquatic invertebrates are commonly used as sentinel organisms for assessment of the effects of environmental pressures on aquatic ecosystems through the measurement of biomarkers. In freshwater ecosystems, numerous studies focused on *Dreissena polymorpha* (Pallas 1771), also known as zebra mussel. *D. polymorpha* is an invasive species originated from Ponto-Caspian region, which spread around the world and is now largely represented in Europe and North-America. In the meantime, the closely related quagga mussel *Dreissena rostriformis bugensis* (Andrusov 1897) became in turn invasive in North America and Western Europe where first observation of quagga mussels was made in 2006 in the Hollands Diep. Molecular genetic markers have then been developed to differentiate *Dreissena* species but such mitochondrial genetic tool (COI-RFLP) doesn't allow to identify potential interspecific hybrids. Zebra and quagga mussels disclose physiological differences such as temperature and salinity tolerance, byssal thread attachment, growth, respiration rates, assimilation efficiency and reproduction. We initiated the characterization of the transcriptomes of both species using NGS technology (Illumina sequencing) to 1) identify new nuclear genetic markers that could be used to clearly identify species and/or hybrids (mainly SNPs), 2) develop a genomic database for *Dreissena* complex and generate a large set of candidate genes showing an strong importance in ecotoxicological studies and 3) generate a SNP database for polymorphism studies. Results presented here describe the main differences observed in two tissues transcriptomes (gills and digestive glands) between the two species studied and gives previous information on putative SNPs that could be used for species identification. We also explicit the main physiological functions identified and highlight set of candidate genes suitable for ecotoxicological purpose.

WE179

Constitution of a reference transcriptomie resource for the copepod Eurytemora affinis and differential expression between sexes exposed to acetone

E. LEGRAND; J. Forget-Leray, A. Duflot, S. Olivier, C. Boulange-Lecomte, SEBIO UNIVERSITY OF LE HAVRE / UMRI SEBIO

Copepods represent the most abundant group of aquatic invertebrates which includes freshwater and marine species. Among them, the calanoid copepod *Eurytemora affinis* is widely represented in the northern hemisphere estuaries and has become a species of interest in ecotoxicology. Like other non-target organisms, *E. affinis* could be exposed to a wide range of chemicals. In this context, we investigated the transcriptome of *E. Affinis* in order to (i) constitute a bank of sequences for *E. affinis* and (ii) highlighted sex-specific patterns in *E. affinis* exposed to solvent acetone as a base for future chemical exposure. After 3 days of stalling, a first sample of 500 copepods (including males, females and young stages) was realized. Then, a solvent (acetone, 0.005% w/v) exposure was performed. After 48h of exposure, 400 males and 400 females were sorted and frozen for further analyses. RNA from non-exposed and exposed organisms were respectively sequenced by 454 GS FLX and Illumina®. *E. affinis* transcriptome was functionally explored using the KEGG pathway database. The differential expression analysis was performed from the acetone samples. Differentially expressed genes (DEG) were investigated after applying a threshold of PPDE (Posterior Probability Differentially Expressed) of 0.95 and a log2(FoldChange) $\geq$ 2. A total of 1,651,761 reads were pyrosequenced. *De novo* assembly resulted in 16,903,584 bases divided in 19,721 transcripts with a mean length of 857 pb. About half of them (9,729) were annotated. 64% of the Blast results were provided by arthropod sequences including crustaceans and insects. 6,446 sequences were identified in 321 pathways. Among them, the category "cellular processes", "environmental information processing", "human diseases", "organismal systems", "genetic information processing" and "metabolism" were illustrated. Moreover, 1,786 DEG were identified between sexes after acetone exposure highlighted sex-specific patterns. 1,072 genes were expressed in females whereas 714 genes were expressed in males.

Sorting the signals: meta-analysis of transcriptome data of zebrafish embryos after chemical exposure

A. Schuettler, Helmholtz Centre for Environmental Research UFZ / Department of Bioanalytical Ecotoxicology; K. Reiche, Fraunhofer Institute for Cell Therapy and Immunology / Bioinformatics Research Unit Department of Diagnostics and

New Technologies; R. Altenburger, UFC Centre for Environmental Research / Bioanalytical Ecotoxicology; W. Busch, Helmholtz centre for environmental research - UFZ / Bioanalytical Ecotoxicology

Adverse effects of chemicals on cells and organisms are in many cases either preceded by or result in gene-expression changes (Nuwaysir et al., 1999). This makes transcriptome analysis a promising tool in ecotoxicological research, e.g. as future bioassay or diagnostic tool for biomontioring. There are several advantages in comparison to established tools, e.g. the non-targeted approach, allowing assessment of several modes-of-action at the same time, or the possibility to combine assessment of adverse effects with identification of effect-drivers, which could also be helpful in the establishment of adverse outcome pathways (AOPs). During recent years several studies analysed global gene expression in *Danio rerio* embryos after exposure to chemicals (Williams et al., 2014). Many of those studies show specific gene-expression changes in zebrafish embryos after exposure to chemicals and claim to offer a proof of concept of the suitability of microarray analysis as potent bioassay. To put the so far published results into context, and analyze the quality and comparability between the studies, we performed a meta-analysis of published transcriptome data. The analysis combined the data of 33 published studies using different chemicals, concentrations and exposure times. The analysis revealed a large heterogeneity in gene expression profiles. In contrary to our expectations no gene could be identified as regulated across all conditions. For sure, heterogeneity can be partly explained by differing experimental designs and the lack of time- and dose resolved data. Since comparability is one major requirement for any OMIC-technology on the way to usability in risk assessment, we propose an experimental design for transcriptomics with time and concentration resolved measurements. Nuwaysir, E. F., Bittner, M., Trent, J., Barrett, J. C., & Afshari, C. a. (1999). Microarrays and toxicology: the advent of toxicogenomics. Molecular Carcinogenesis, 24(3), 153–9. Williams, T. D., Mirbahai, L., & Chipman, J. K. (2014). The toxicological application of transcriptomics and epigenomics in zebrafish and other teleosts. Briefings in Functional Genomics, 13(2), 157–71.

The psychotropic family of pharmaceutical impact the freshwater organisms

J. MAZZITELLI, Centre Universitaire Jean-François Champollion, Albi, France / UMR CNRS; E. BONNAFE, J. Malgouyres, Centre Universitaire JeanFrançois Champollion Albi France; F. Geret, Centre Universitaire JeanFrançois Champollion Albi France / UMR   CNRS

Aquatic organisms are frequently exposed to a wide diversity of chemical compounds suspended or absorbed on substrates. These compounds such as pharmaceuticals are released into aquatic environment from either industrial or domestic effluent. Most of chemicals, especially psychotropic pharmaceuticals, are very persistent even after biotic and abiotic treatments in environment and waste water treatment plant (WWTP). Despite of the important occurrence of detection, few study concern the aquatic environmental impact. Among the aquatic biodiversity, are the molluscs, broadly studied for their grade in the food chain (primary consumer), but also because of their low celerity. *Radix balthica* is a freshwater mollusc present in many French rivers, allowing easy sampling of this snail for eggs collection. The flatworms including *Schmidtea polychroa,* belong to benthic invertebrate and are also studied as ecotoxicological model due to their range in the food chain. Dugesidae is a genus broadly studied, first for their ability of regeneration and secondly for their range in the food chain (secondly consumer). The aim of this study was, to evaluate the toxicity of four psychotropic drugs from four different therapeutic classes and three chemical families. Oxazepam (anxiolytic, benzodiazepine), carbamazepin (antiepileptic, benzodiazepine), cyamemazin (neuroleptic, phenotiazin) and sertralin (antidepressant, Inhibitor Selective of Reuptake of Serotonin (ISRS)) have been selected because of their frequencies and their presence in the French WWTP effluents. Pharmaceuticals toxicity was evaluated on *R. balthica* embryos using hatching success and hatching delay on a concentration range from environmental concentration to 100μg/L. For instance, these indicators showed an effect from 1μg/L to 100μg/L for oxazepam. A differential RNAseq method and an RT-qPCR validation were released on *R. balthica* exposed of oxazepam at 10μg/L and 0.815μg/L or to reconstituted water for control. Statistical analyses have shown 144 contigs differentially expressed for the 10μg/L condition. Among these differentially expressed contigs, we have highlighting several pathways impacted. Pharmaceutical impact was also evaluated on the movement, reproduction ability and regeneration integrity of *Schmidtea polychroa*. Only the movement and the reproduction results showed significant differences to the control. The RT-qPCR study is in progress for targeting the transcriptomic responses relating to the phenotypic responses.

WE182

A Combined Targeted/-non-Targeted Metabolomics approach using UHPLC-Oribtrap- MS: Method validation and ecotoxicological applications

A. Ribbenstedt, Stockholm University / Department of Environmental Sciences and Analytical Chemistry ACESO; M. Åberg, ITM Stockholm University / Department of Environmental Sciences and Analytical Chemistry ACESO; J. Benskin, Stockholm University / Environmental Science and Analytical Chemistry

Characterization of the naturally occurring small molecules in a biological sample(i.e. the metabolome) has shown great promise in ecotoxicology for characterizing chemical modes-of-action, fingerprinting toxicant exposure, or redefining low dose effects levels. Metabolomics can be carried out using either a targeted approach, involving a full complement of standards, or non-targeted approach, in which analysis is carried out in open scan and individual peaks are identified through massspectral library\nmatching. Advantages of the former include generation of quantitative data and improvements in accuracy and precision, while the latter offers the possibility of discovering novel biomarkers.Few have attempted to combine these approaches in order to quantify known metabolites,while also capturing data on novel biomarkers. \nHere we report on the development of a novel targeted/non-target metabolomics approach using ultra-performance liquid chromatography-high resolution (Orbitrap) mass spectrometry.The method facilitates targeted, quantitative analysis of 20 amino acids, 10 non-proteinogenic amines, 7 biogenic amines, 7 TCA-intermediates, and 10 nucleobases and neurotransmitters in multiple reaction monitoring mode, while simultaneously collecting high resolution (Rs>100,000), accurate mass (< 1ppm) data in open scan (m/z100-1000) to facilitate novel biomarker ID. Three methods were developed to maximize metabolite coverage: The first 2 methods employed C18 (1.8μm, 2.1x 100mm) and HILIC (1.7 μm,2.1 x\n100mm) stationary phases with trifluoroacetic acid and acetonitrile mobile phases for determination of non-lipid metabolites.The third method utilized flow injection-MS/HRMS with isotopic overlap deconvolution for determination of >150 lipids (including carnitines, glycerophospholipid and\nsphingomyelins). The benefits of HRMS for FI-MS/MS-based lipidomics were assessed by comparing results with those obtained using the identical method run on a quadrupole mass spectrometer. Non targeted data for all analyses were processed using TracMass2 and MetaboAnalyst. This method is among the first to combine a combined targeted/non targeted approach to obtain quantitative information on known metabolites, while offering the possibility of novel biomarker ID.

Emission from intensive livestock can affect health of living organisms. The presence of 3-methylindole (3MI), a substance found in mammalian faeces, in contaminated groundwater migh negatively affect physiological processes in fish. Currently, no information is available on 3MI metabolism by fish. We investigated 3MI metabolism by two fish species, carp and rainbow trout, at two ages. Hepatic microsomes from fish were exposed to four concentrations of 3MI (from 2 to 100 μM). Rainbow trout produced two metabolites, 3-methylindole (3MOI) and indole-3-carbinol (I3C), while carp produces only 3MOI. The rate of 3MOI production was similar in both species at both ages. The rates of metabolites formation from 3MI in the presence of specific chemical inhibitors indicated that the CYP450 isoforms CYP1A and CYP3A are mainly responsible for 3MI metabolism. In summary, 3MI is metabolised in fish livers to 3MOI and I3C by CYP450, and formation of these metabolites might be species-dependent. Keywords: 3-methylindole; 3-hydroxy-3-metyloxindole; indole-3-carbinol; cytochrome P450 Acknowledgement - This work was financially supported by the Ministry of Education, Youth and Sports of the Czech Republic – projects “CENAKVA“ (No. CZ.1.05/2.1.00/01.0024) and “CENAKVA II“ (No. LO1205 under the NPU I program), by the Grant Agency of the University of South Bohemia in Ceske Budejovice (No. 012/2016/Z), by the Czech Science Foundation (No. 15-04258S), and by a research grant from C.F. Application of transgenic zebrafish in adverse outcome pathway analysis: a case study on bisphenol A

A. Brown, Exeter University / Biosciences; L. Gunnarsson, University of Exeter / Biosciences; J. Green, University of Exeter / College of Life and Environmental Sciences; S. Mourabit; m. hetheridge, ExeterUniversity / Biosciences; R. Currie, Syngenta; C. Tyler, Biosciences College of Life and Environmental Sciences

More than 1000 chemicals are known, or suspected, to interact with hormone receptors, and/or to affect hormone metabolism[1], and some of these molecular initiating events (MIEs) may lead to adverse effects on a wide range of developmental processes and physiological functions. However, only a small fraction of chemicals have been investigated for endocrine disrupting effects in intact organisms[2]. Although *in silico* and *in vitro* tools provide some indication of the potential endocrine activity of chemicals, reliable *in vivo* systems are required to assess for adverse effects. Transgenic (TG) animal models (e.g. zebrafish) provide *in vivo* systems, in which MIEs triggering adverse outcome pathways (AOPs) can be identified and quantified by fluorescent protein reporters linked to specific receptors or enzymes. Spatial resolution of MIEs at the organ and tissue levels in larval TG zebrafish facilitates targeted assessment of downstream molecular events and subsequent physiological and functional responses. Here we present a case study on embryo-larval TG zebrafish exposed to the estrogenic plasticiser bisphenol A (BPA) previously reported to affect brain development and function at or below aqueous exposure concentrations (230 μg/L) leading to tissue concentrations (^{3}10 μg/kg), which are equivalent to mean human placental concentrations and maximum daily doses for bottle fed infants[3,4]. Using TG(ERE-Casper) zebrafish, which combine a reporter system for indicating Estrogen Response Element activation throughout the body[5] in a translucent Casper phenotype, we show that BPA (100, 1000 μg/L) and its metabolite MBP (0.25, 2.5, 25 μg/L) target the heart valves, with consistent ERE expression at 4 and 14 days post fertilisation (dpf). Via assessments of differential gene expression (using RNA-seq) in micro-dissected heart tissues obtained from treated and control fish at 4 and 14 dpf, and a series of cardio-vascular and other functional endpoints (e.g. heart beat rate, blood flow, critical swimming speed at 14 dpf), we attempt to define AOPs for the two test compounds. Proteomic analysis of the estuarine copepod, Eurytemora affinis, in response to endocrine disruptors

E. LEGRAND; J. Forget-Leray, A. Duflot, G. Tremolet, SEBIO UNIVERSITY OF LE HAVRE / UMRI SEBIO; J. Thome, Liege University / Laboratory of Animal Ecology et Ecotoxicology; C. Boulange-Lecomte, SEBIO UNIVERSITY OF LE HAVRE / UMRI SEBIO

Aquatic ecosystems constitute the chemicals' final destination. One of the chemicals' families targeted by the EU Water Framework Directive is pesticides due to their endocrine disruption (ED) potential. Nowadays, ED effects of chemicals are well documented in vertebrates. Few data are available on invertebrates whereas they represent 95% of the wild fauna. In this context, we investigated the proteomic responses of the widespread copepod *Eurytemora affinis* to model pesticide exposures, in order to (i) improve the knowledge on their effects in crustaceans and (ii) evaluate the potential of proteomic analysis to develop molecular biomarkers of endocrine disruption. After 3 days of stalling in the laboratory, copepods were divided into three 10-liter aquariums. Copepods were exposed to sublethal concentrations of pyriproxyfen (PXF, 10μg/L) and chlordecone (CLD, 10μg/L) separately and in binary mixture (PXF; CLD, 2.5 μg/L; 3.75μg/L respectively). A solvent (acetone 0.005% w/v) control was used. After 48h of exposure, males and females were sorted and frozen for further analyses. After extraction, proteins were identified by HPLC coupled to mass spectrometry (GC-MS-MS). Analyses were performed for both genders for each contamination in order to identify sex-related responses. 1,092 proteins were identified using the GC-MS-MS procedure. The cluster analysis highlighted two groups corresponding to gender. Male and female copepods were specifically more impacted by PXF and CLD respectively. Finally, 76 proteins were differentially detected between conditions including 25 proteins under-expressed and 51 over-expressed. Proteins were involved in several processes such as energetic metabolism and defence. We have focused our investigation on proteins involved in reproduction, growth and development in response to EDs. For example, proteins involved in reproduction like vasa or thioredoxine were under-regulated in male copepods highlighting a potential disruption of gametogenesis. Furthermore, muscle activity with actin and myosin were under-regulated in male copepods, suggesting an impact on locomotion

WE186

Screening of pesticides, alone and in binary mixtures, for ecdysteroid hormone agonist and antagonist activity using the Drosophila cell-based (S2) reporter assay.

E. LEGRAND; J. Forget-Leray, SEBIO UNIVERSITY OF LE HAVRE / UMRI SEBIO; N. Yu, G. Smagghe, Ghent University / Department of Crop Protection; L. Swevers, National Centre for Scientific Research Demokritos / Insect Molecular Genetics and Biotechnology; A. Poret, A. Duflot, C. Boulange-Lecomte, SEBIO UNIVERSITY OF LE HAVRE / UMRI SEBIO

Aquatic ecosystems constitute the chemicals' final destination. One of the chemical families targeted by the EU Water Framework Directive is pesticides due to their endocrine disruption (ED) potential. Nowadays, ED effects of chemicals are well documented in vertebrates and the Organization for Economic Co-operation and Development (OECD) recommends the use of human receptor assays for the screening of ED chemicals. Few data are available on the ED effects on invertebrates whereas they represent 95% of the wild fauna. In this context and in order to explore the effect of endocrine disruptors on invertebrate metabolism, we investigated the potential agonist and antagonist effect on the ecdysteroid receptor for five pesticides known as endocrine disruptors, alone and in a binary mixture using an in vitro test.\nIn this project we used chlordecone (CLD), vinclozolin (VZ), tributyltin (TBT), pyriproxyfen (PXF) and methoprene (MP), as vertebrate and invertebrate models of endocrine disruptors. Of each product a range of different concentrations (from 1.5.10-1 M-1 to 3.10-8 M-1) was tested for investigating their agonist/antagonist potential. Drosophila S2 cells were firstly transfected with the pERE-GFP-ERE-Luc construct composed of ecdysteroid hormone response elements and the reporter luciferase gene. Then the agonist and antagonist activities were tested in 96-well microplates.\nNo agonist activity was observed for each compound alone. Cell toxicity appeared for the highest concentrations. An antagonism was detected for PXF and MP. As juvenile hormone agonist, interaction with the ecdysteroid receptor could be expected. Moreover, CLD – known as an estrogen receptor agonist – may present a weak antagonist activity. TBT did not act as an antagonist of the ecdysteroid receptor. No agonism was observed for any binary mixture and toxicity appeared for the highest concentration. All the binary mixtures showed an antagonist activity. However, interaction between chemicals could induce a response which could be not specific to the ecdysone receptor.\nIn conclusion, the cell-based reporter assay for screening ecdysteroid receptor agonists/antagonists highlighted antagonist activity for both vertebrate and invertebrate models of endocrine disruptors. Binary mixture showed also antagonist activity. However, this response could be non-specific to the receptor. The usefulness of in vitro tests is discussed in relation to predict activities of mixtures in the ecosystem.

Epigenetic and evolutionary effects of pollutants: new challenges for long-term ERA (P)

Changes in DNA methylation in response to cyanobacteria in the model crustacean Daphnia

J. Asselman, Ghent University / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; D. De Coninck, Ghent University / Laboratory of Environmental Toxicolgy Aquatic Ecology; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; K. De Schamphelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

Despite the recent developments in molecular technologies, little attention has been given in environmental toxicology to epigenetic modifications and their potential consequences for environmental risk assessment. We focused on the crustacean *Daphnia* whose well-known ecology and phenotypic plasticity offer unique opportunities to enhance our understanding of epigenetic mechanisms and their importance in environmental challenges. We characterized the methylation pattern in *Daphnia* in response to a rich diet and a diet contaminated with the toxic cyanobacterium *Microcystis aeruginosa*, a common harmful algal bloom known to have detrimental effects on higher organisms. We used bisulfite sequencing to identify methylated cytosines in genomic features. Methylation was primarily targeted to exonic regions while introns and intergenic regions were generally devoid of methylation. We observed that despite the low methylation level in *Daphnia,* some genes are preferably methylated with methylation levels higher than 50% while others have no methylation at all. Roughly 300 genes were differentially methylated between the two treatments. This geneset included ribosomal proteins and RNA polymerases as well as histones and methyl-binding proteins suggesting a functional role for DNA methylation in gene regulation. Overall, the results suggest that DNA methylation may play a significant role in environmental stress responses in *Daphnia*.

WE188

Transgenerational effects of a chronic external gamma irradiation on Daphnia magna: epigenetic modification and inheritance

M. Trijau, IRSN/PRP-ENV/LECO / PRPENVSERISLECO; F. Alonzo, C. Adam-Guillermin, IRSN

Aquatic and terrestrial ecosystems are exposed to radionuclides through planned discharges or accidental releases linked with the nuclear industry activities. Over the past decade, ecosystems protection against ionizing radiation has become a growing public, regulatory and scientific concern. Nowadays, ecological risk assessment for ionizing radiation is still based for a vast majority on studies investigating effects under acute doses and short exposure time, far from realistic environmental conditions in which natural biota are actually exposed. Recently, studies in daphnids at chronic low doses have been conducted over several generations in order to increase our understanding of the long-term effects of low doses of gamma radiation and explore underlying molecular mechanisms. In this context, radio-induced epigenetic modifications have never been investigated in invertebrate species although it was shown that ionizing radiation can induce changes in DNA methylation patterns and gene expression. Epigenetic changes imply the possibility that modifications might be inherited across generations. The present study (still in progress) examines the potential transmission of epigenetic alterations from gamma irradiated daphnids to their non-irradiated progeny up to the third generation (F1, F2, F3). Using the cladoceran crustacean Daphnia magna as a model organism, our objectives are threefold: (i) to examine whether environmentally relevant doses of gamma radiation (0.01 and 35.4 mGy.h-1) received by parents will induce effects on survival, growth and reproduction over non-exposed generations, (ii) to test possible epigenetic modifications caused by gamma irradiation and its transmission to non-exposed generations, (iii) to compare responses to chronic gamma radiation between the molecular and organism levels.

WE189

Crossing scales: From genes to the phenotype and back in ecotoxicological extrapolation for genetic and epigenetic effects - the next frontier

J. Ackerly; D. Efetov, Seton Hall University / School of Arts and Science

Proper Science (PS) relies on methods and methodologies that provide tools to extrapolate findings across varying scales. Scales can include organisms, environments, space and time. In Ecotoxicology and Climate Change Science, the issue of extrapolation presents a pivotal challenge to assess the risks of chemicals and other stressors in the environment. Evolution acts on scales different to the genetic and epigenetic effects of toxicants. As a consequence, extrapolation is a formidable temporal problem that may determine speciation, defined as in Hubbell (2001), and furthermore disrupt the genetic diversification triggers. Moreover, assessing the risk for chemicals from the environment remains a debatable target of modern approaches to risk assessment. In our poster we introduce the Daphniapolator, a model that allows transiency of temporal and spatial boundaries to assess risks on selected scales by the user from genes to ecosystems. We demonstrate the feasibility of our approach for an emerging contaminant, next generation carbon nanotubes (NGCT), extrapolating from epigenetic risk to whole ecosystems. The predictive toolbox of the model is based on closed-form solutions of the elementary stochastic differential equations (ESDE), as well simulation techniques including Levy jump process, variance reduction techniques, and pseudo-regression approaches with Martingale stochastic processes (with non-normalized semi-Gaussian regressors). Calibration data originates from population genetic studies in the wild with collembolans under exposure from sewage treatment plants estimating no consequence effect concentration (NCEC) using a reverse Bayesian spatially and temporally explicit model (RBSTM). Data were collected using good laboratory practice (GLP) procedures. We discuss options for extrapolation to other species, across time scales and alleles in the gene pool. We conclude that our model approach represents a very promising approach to unite current challenges in ecotoxicology regarding genome, epigenome, proteomics, metabolic extrapolation problems and issues of pre-selected inference under toxicant stress. Future studies should scrutinise the model application for different problems, scales, compounds and calibration data.

Most eco-toxicological test guidelines only evaluate the effects observed within one generation, thus disregarding those potential detrimental effects that may appear across generations. The toxicological potential of contaminants may either decrease or increase across generations, or even remain unchanged. Reproductive toxicity in mammals monitors the effects on the parental generation as well as on their offspring. In fact, there are already standardized test procedures aimed to assess multigenerational effects for mammals and fish, but there are no equivalent tests for invertebrates, despite that their short life-cycles offer to cost-effectively monitor multigenerational effects of toxic substances in individuals and populations. Here we described the activities that are currently been conducted on behave of the SETAC EVOGENERATE Working Group to set up protocol for a two generation Daphnia magna reproduction test and to test the performance of that protocol across up to 20 different labs from Europe, America and Asia. Indeed this is one of the largest conducted intercalibration tests ever conducted using the OECD 2011 guideline. We aimed to develop a two generation test with only few amendments of the already existing guidelines. The few modifications included to start the second generation with third brood neonates collected from reproducing females from the first generation. We selected pyperonil butoxide as a test chemical based on previous studies that showed that this compound was the best candidate among other two compounds. To minimize interlab variability all laboratories used the same stock solutions, which were prepared by one of the partners and send it the rest of partners. The results obtained in this intercalibration test will be discussed in this poster.

WE191

Maternal nanoparticle treatment induces multi-generational effects in the nematode Caenorhabditis elegans

S. Kim, Konkuk University; J. Moon, Konkuk Univesity; Y. An, Konkuk University / Department of Environmental Heath Science

Organisms produce offspring during the whole of their reproductive life cycle; however, changes in age or environmental conditions may alter physiological characteristics of the parental generation. These changes might result in altered responses to environmental challenges, such as nanoparticles, and might be manifested as phenotypic effects in the offspring. Here, we provide evidence of multi-generational effects following exposure of *Caenorhabditis elegans* to quantum dot (QD) nanoparticles. We identified four groups of F_1 offspring from the treated parental generation based on the timing of their production: first spawning, first appearance of the bag of worms (BOW) phenotype, serious BOW, and lethal BOW. In the F_2 generation derived from the latter group, early reproductive senescence was observed; this effect was associated with abnormal germ cell proliferation during early development. We suggest that RNA interference mechanisms are associated with the lethal BOW phenotype and induce a transgenerational effect that causes reduced F_2 fertility.

Structural and Functional Biomarkers to assess nanomaterials-associated environmental risk

C. Fajardo; G. Costa, Universidad Complutense de Madrid; S. Sanchez-Fortun, M. Nande, UCM; M. Martin, Universidad Complutense Madrid

Advances in environmental biotechnology have allowed the characterisation of soil organisms, and the measurements of gene and/or protein expression levels upon exposure to chemical stressors, such as engineered nanomaterials (ENMs). The forecasted growth in the manufacture and use of these nanomaterials makes it likely that increases in environmental exposure to ENMs will occur, whereas the toxicological effects of nanomaterials on environmental biota, soil health and functionality remains mostly unknown. A microbial ecotoxicological approach based on the response of soil microbial communities offers the opportunity to evaluate the impact of nanomaterials on natural populations, and it leads consequently to a better environmental risk assesment. Recent innovative breakthroughs in genotypic profiling, ultrafast genome pyrosequencing, metagenomics, metatranscriptomics, metaproteomics and metabolomics along with bioinformatics tools have provided crucial in-sights of microbial communities and their mechanisms to cope with environmental pollutants. Likewise, molecular microbial biomarkers or bioreporters have been developed for in situ detection/ monitoring of environmental pollution. **Structural Biomarkers:** Multiple group-specific rRNA probes targeting prokaryotic and eukaryotic microbial taxa can be used in a **FISH** experiment for simultaneous phylogenetic classification of physiologically active microbial populations in an environmental sample. **Metagenomics** based methods have been useful to determine novel gene families and or microbes involved in bioremediation of xenobiotics. Availability of whole genome sequences from several environmental microorganisms has been useful to determine the gene pool of enzymes involved in the microbial response to anthropogenic pollutants. **Functional Biomarkers: Transcriptomic** or metatranscriptomics tools are used to gain functional in-sights into the activities of environmental microbial communities by studying their mRNA transcriptional profiles. **Proteomics** based investigations have been useful in the identification of key proteins involved in the physiological response of microorganisms when exposed to anthropogenic pollutants (e.g. ENMs). Here we show results of the application of some of these molecular techniques in linking the structure and function relationships of microbial communities and for biological sensing of pollution at ENMs contaminated sites.

WE193

Reprotoxic effects of microcystin-LR and microcystin-producing Microcystis extract on adult medaka fish

Q. QIAO, UMR; B. MARIE, CNRS / MNHN MCAM, Muséum National dHistoire Naturelle, Paris / UMR

The massive cyanobacterial blooms threaten human health as well as any living organisms in aquatic environment, particularly due to the production of natural toxic components, so-called cyanotoxins. One of the most characterized cyanotoxins are the microcystins (MCs) that can cause a severe hepatotoxicity. In recent years, the potential reproductive toxicity of MCs has been also explored by several laboratories. The chronic exposure to MCs may threaten Human reproductive health via consumption of MCs–contaminated water or fish. In the present work, we investigated the reprotoxic effects of MCs and MC-producing *Microcystis* extract on adult medaka. Medaka were exposed to pure MC -LR 1, 5 $\mu g.L^{-1}$ and MC-producing *Microcystis* extract with 5 $\mu g.L^{-1}$ of equivalent MC-LR for 28 days. Various reproductive parameters including the fecundity, the fertilization success and the egg hatchablity were examined during the exposure, revealing negative effects induced by MC-LR. In addition, sex hormones and vitellogenin levels in plasma were also affected by the exposure. Histological observations indicate that hepatocytes present glycogen storage loss together with cellular damages. Transcriptome profiling of liver was performed using Illumina RNA-seq and around 5M unique reads per library were mapped to the reference genome of medaka. Differential expression analysis identified over 100 disregulated genes from 5 $\mu g.L^{-1}$ MC-LR and MC-producing *Microcystis* extract treatments and gene ontology enrichment analysis reveals that response to stimulus, metabolic process and transcription regulator are highly affected in both females and males. RT-qPCR has been used to investigate the transcriptional level of 10 related genes in gonad. Furthermore, proteomics profiling of liver by using iTRAQ indicates that a set of proteins involved with lipid metabolism, amino acid metabolism, generation of energy and choriogenin/vitellogenin syntheses were statistically significantly different from those of controls. A sex-specific response was implied from both transcriptomics and proteomics profiling. The outcomes obtained through this study will advance our current knowledge on the range and severity of reproductive toxicity and to explore risks on aquatic vertebrate models due to cyanotoxins, that could be further discussed with regard with Human health.

WE194

Microbial community molecular analysis and sequencing linked to mixtures of chemical compounds

V.E. Ferrero, LGC; R. Loos, European Commission Joint Research Centre / Institute for Environment and Sustainability; S. Tavazzi, European Commission Joint Research Centre / Institute for Environment and Sustainability IES; M. Sacca, National Research Council of Italy / Water Research Institute; P. Grenni, National Research Council of Italy (CNR) / Water Research Institute; M. Di Lenola, N. Ademollo, National Research Council of Italy / Water Research Institute; L. Patrolecco, Water Research Institute-National Research Council / Water Research Institute; A. Barra Caracciolo, National Research Council of Italy / Water Research Institute; J. Huggett, LGC; t. lettieri, European. Commission - Joint Research Centre / Institute for Environment and Sustainability IES

In Europe, the good quality of surface waters is established under the Water Framework Directive (WFD) based either on the chemical monitoring or on the ecological status. There is a growing concern about the combined action of pollutants present in waters. The European Commission is then asking for a stronger effort to ensure that the risks associated with chemical mixtures are better understood and assessed. The correlation between the chemical composition and the microbial population is not straightforward understandable. Tiber River was selected for a pilot study to characterise the microbial profile of three areas differently influenced by anthropogenic pressures (agricultural, urban and industrial) and one pristine area. Water samples were collected from four sampling sites during two seasonal periods (April and October). Tiber River samples were characterized from chemico-physical point of view. Chemical analyses focused on pesticides including biocides and insecticides, benzotriazole, corrosion inhibitors (high production volume chemicals), pharmaceuticals, antibiotics, and perfluoroalkyl substances (e.g. PFOS; PFOA). Chemical analyses revealed low concentrations of pesticides in the agricultural area of Attigliano (sampling point 2). Emerging contaminants (benzotriazoles, pharmaceuticals, perfluoroalkyl substances) were particularly found at the sampling point 3 in the River Aniene in Rome (industrial impact) and sampling point 4 in the Tiber River close to the river mouth, downstream of the urban waste water treatment plant of Southern Rome. In order to link these results to the ecological status of the river, molecular analysis (qPCR-based detection of bacteria, cyanobacteria and protozoans) were also performed in parallel with 16s and shotgun sequencing of the metagenomes of the river microbial community. Concentrated water samples were sequentially filtered using 20 μm, 5 μm and 0.22 μm filter membranes. The microbial community genomic DNAs were extracted from the 0.22 μm filters. A fragment of the 16s rDNA region was amplified and sequenced. To better evaluate bacterial diversity along the river also shotgun sequencing was performed. Based on the results obtained from the 16s and shotgun sequencing, some targeted microorganisms were selected for qPCR assays to find out the potential correlation with the chemical analysis.

WE195

Measuring microbial interactions in soil in high throughput

M. Dubey, University of Lausanne / DMF; J. van der Meer, University of Lausanne / Department of Fundamental Microbiology

Microbial ecosystem engineering approaches often rely on the introduction of one or more selected species into an existing microbial community. The success of introduced species to a large extent depends on the types of interactions that it is developing with other existing microbes, such as neutralism, commensalism, syntrophism or competition. Deciphering the rules governing microbial species' interactions is a strenuous task. Our project is focused on better understanding the principles of success of establishing pure cultures in complex microbial ecosystems such as contained within soil. Here we develop a high-throughput co-cultivation approach that might enable us to study the species' "interactome", the identification of favourable and non-favourable species combinations that decide on the survival of the inoculant in the community. We use agarose micro-beads as growth chambers to randomly combine soil community members with or without pure culture inoculants. Growth of co-cultured species members is followed by microscopy and enables a global overview of potentially positive effects of the inoculant on growth of the members in the soil on specific carbon substrates. In addition, the “interactome” study allows detecting possible species pairs, negative or positive, that can be recovered and identified in detail. The resulting knowledge not only provides ample data in designing functional synthetic communities but also construct new avenues for “synthetic ecology”. \n

The bactericie triclosan affects 16S and 18S rRNA diversity and composition in marine periphyton communities

K. Sanli, University of Gothenburg / Department of Biological and Environmental Sciences; A. Eiler, L. Sinclair, Uppsala University / Department of Ecology and Genetics; N. Corcoll, University of Gothenburg / Department of Biology and Environmental Sciences; H. Nilsson, University of Gothenburg / Department of Biological and Environmental Sciences; H. Johansson, T. Backhaus, University of Gothenburg / Department of Biology and Environmental Sciences; E. Kristiansson, Chalmers University of Technology / Department of Mathematical Statistics; M. Eriksson, Chalmers University of Technology / Department of Shipping and Marie Technology

Modern DNA sequencing platforms have an enormous throughput at a lower cost than ever before. The possibility to multiplex and barcode PCR amplified gene fragments, and sequence them in the same run can further lower the cost per sequencing depth. This approach, *amplicon sequencing*, has great potential to detect adverse changes in the structure of toxicant-exposed microbial communities. Here we investigate the long-term effect of the bactericide triclosan (TCS) on the 16S and 18S gene richness, diversity and composition of marine periphyton communities. A long-term (17 days) flow-through microcosm experiment with constant TCS exposures of 0 – 316 nM was performed. DNA was extracted using the FastDNA spin kit (initially developed for for soil communities) and we performed multiplexed amplicon sequencing using the Illumina platform. In total 313,855 16S and 176,566 18S sequences were retrieved and the sequences were clustered into 1789 and 509 Operational Taxonomic Units (OTUs), respectively. The prokaryote part of the communities was dominated by the phyla *Proteobacteria*, *Bacteroidetes* and *Planctomycetes*, whereas the eukaryote part was dominated by *Arthropoda*, *Bacillariophyta*, *Chytridiomycota*, *Cercozoa*, *Mollusca* and *Ciliophora*. TCS exposure resulted in a decrease of 16S richness and diversity, and a changed 16S composition, at an exposure of 31.6 nM and above. In the concentration interval of 1 – 10 nM more subtle changes in the overall 16S composition were detected. For *Proteobacteria* and *Bacteroidetes*, the richnesss and diversity followed a bi-phasic concentration response curve with a clear decrease between 3.16 nM and 31.6 nM, but with a much smaller decrease at 316 nM. This might be an indirect effect from a changed 18S composition at 316 nM. Unfortunately, we do not have 18S data for the exposure interval 10 – 100 nM and hence cannot compare the sensitivity of pro- and eu-karyotes. In general, the 18S composition was more variable than the 16S composition. Still, the TCS exposure resulted in a decrease of the 18S richness and diversity, and a changed 18S composition, at an exposure of 316 nM. Based on richness and diversity, the eukaryotic taxa *Viridiplantae* was sensitive whereas *Stramenopiles* was insensitive to TCS. In this study we demonstrate that triclosan has adverse effects on microbial community composition and that amplicon sequencing is a suitable method to describe toxicant-induced changes in community structure to a reasonable cost.

Challenges in Environmental Assessment of Cosmetics and Personal Care Products (P)

WE197

Importance of Preserving Environmental Risk Assessment (ERA) of Personal Care Products

I. Davies, Personal Care Products Council / Science; A. Carrao, Kao USA / RD

ERA is the process by which exposure and hazard of a material are quantified.

Within such an assessment, environmental occurrence, fate and ecological effects are assessed *via* standard test guidelines, such as those prescribed by the OECD (Organization for Economic Cooperation and Development), or by high quality non-standard experiments. Testing strategies are often tiered, meaning that a number of screening level or modeling methods (such as QSARs, or quantitative structure activity relationships) can be used to prioritize materials for further, more in depth testing. This approach is cost effective and reduces unnecessary animal testing. The result is the generation of a PEC (predicted environmental concentration) and a PNEC (predicted no effects concentration). \n \n Next, a risk characterization ratio (RCR) is derived by dividing the PEC by the PNEC value. The RCR can be either >/< 1 (or in rare cases = 1). If a value of < 1 is calculated, then a material is likely to pose an acceptable environmental risk. Conversely, if an RCR >/= 1, then an unacceptable environmental risk will be posed by the material. \n \n ERA is widely prescribed by a number of major global regulatory bodies and frameworks. These include the USEPA, USFDA, ECHA and VICH. A large number of structurally and functionally diverse materials have therefore been assessed by risk-based methods, or are currently being assessed in this manner. As such, ERA represents a widely used, scientifically relevant and reliable means of determining materials which may be of environmental concern. \n \n Despite the availability and proven utility of ERA methods in identifying materials of potential concern, a number of regulatory and legislative schemes in the US and Europe have abandoned an ERA-based approach when assessing environmental impacts of consumer chemicals. In particular, hazard and exposure data are often considered in isolation. This therefore results in regulatory and legislative decisions being taken without a full comprehension of how a material may impact a specific environment. Moreover, alternative compounds, which are then needed to replace controlled materials, can sometimes pose more of an environmental risk. These are called regrettable substitutions. \n \n This poster will discuss the benefits of ERA compared with only considering hazard or exposure. We will also use examples of regrettable substitutions to highlight instances for which comparative ERAs may have avoided these from occurring.

WE198
PBT Behavior and Aquatic Ecotoxicity of Personal Care Products: QSAR modeling and prioritization
P. Gramatica, S. Cassani, A. Sangion, University of Insubria / DiSTA
Several ingredients in Personal Care Products (PCPs) are now of recognized environmental concern for their increasing presence in aquatic compartments. These ingredients have heterogeneous chemical structures and very different properties, but for the majority of them persistence and toxicity data are lacking. Moreover, the determination of all the dangerous properties, required by REACH and Cosmetics Directive, is a long and difficult task. Due to the high variety of these chemicals and the big number of end-points that should be studied, it is important to have tools useful to highlight the most harmful compounds, focusing the experiments only on these. In this study we propose tools for prioritizing the most dangerous ingredients in PCPs, thus reducing the costs and the animal tests as required by the new Regulations. More than 500 PCPs (fragrances, parabens, phthalates and UV filters) have been screened for their cumulative PBT behavior and for their acute aquatic toxicity on algae, Daphnia and fish. This screening has been done by QSAR models (consensus between PBT-Index in the software QSARINS and US-EPA PBT Profiler) and by *ad hoc* developed QSARs on *P. subcapitata*, *D. magna* and *P. promelas* toxicity. Toxicity predictions were combined by Principal Component Analysis and MultiCriteria Decision Making identifying a cumulative toxicity trend, further modeled by theoretical molecular descriptors as an aquatic toxicity index (ATI). A priority list containing the PCPs identified as the potentially most hazardous, both for PBT behavior and aquatic ecotoxicity, is proposed. The PCP ingredients identified as the most dangerous are mainly UV filters, in particular with benzotriazole rings. The results of this screening/ranking are a valid help to assess the ecological risk of PCP ingredients, belonging to various chemical classes, and to reduce and focus experimental tests.

WE199
Legal gaps in the European chemical legislation impede environmental risk assessment and risk management of personal care products
U. Klaschka, University of Applied Sciences
Some features in the REACH- and the CLP-Regulation seem to be designed especially for products like personal care products with the intention to improve protection of the environment and of human health. However, a closer look reveals several exception provisions with the effect that these rules need not to be applied to cosmetics. Cosmetics are special. But are the exceptions in the European chemical legislation justified? A comparison of the REACH- and the CLP-Regulation with the Cosmetics Regulation reveals that the Cosmetics Regulation cannot compensate for these caps. Several studies show that this situation impedes a decent hazard and risk assessment of personal care products and ingredients.

WE200
Natural substances in personal care products
U. Klaschka, University of Applied Sciences
Natural personal care products enjoy great public acceptance today. Is this bonus justified? Natural substances in personal care products are used in increasing amounts. Most of them are complex mixtures of natural compounds belonging to various chemical substance classes. A large number is classified as dangerous for human health and the environment and many constituents are known for their potent physiological effects. A market study revealed the big variety of natural substances used in personal care products. It also showed that many dangerous natural substances are indeed used today. However, the most frequently employed natural substances are not classified as dangerous, such as Xanthan gum, *Simmondsia chinensis* oil, *Helianthus annuus* seed oil or *Butyrospermum parkii* butter. (Eco-)Toxicity of multi-constituent substances like natural substances is caused by the constituents. Some constituents of the natural substances found are chemically identical to industrially synthesized chemicals.. In cases where the constituents are known, the classification as dangerous for the aquatic environment of the natural substance can be calculated following the procedure of the CLP regulation for mixtures. There is no scientific reason why natural ingredients in personal care products should in general be regarded as less hazardous compared to synthetic ingredients.

WE201
Statistical analysis of siloxanes in biota and sediments in the Inner Oslofjord 2011-2014, with emphasis on D5
M. Schøyen, Norwegian Institute for Water Research (NIVA) / Centre for Coastal and Marine Research; S. Øxnevad, D. Hjermann, Norwegian Institute for Water Research NIVA; C. Mund, T. Böhmer, K. Beckmann, Evonik Nutrition & Care GmbH; D.E. Powell, Dow Corning Corporation / Environmental Sciences
Cyclic volatile methylsiloxanes (cVMS) in biota and sediment of the Inner Oslofjord in Norway have been monitored since 2011 to determine if concentrations are stable or changing following a temporal trend. Cod (*Gadus morhua*), herring (*Clupea harengus*), shrimp (*Pandalus borealis*) and sediment were analysed for octamethylcyclotetrasiloxane (D4), decamethylcyclopentasiloxane (D5) and dodecamethylcyclohexasiloxane (D6). Cod (46-55 cm) were analysed individually (2011, 2012) or as pooled samples (n=3 in 2013, 2014). Herring (Mean concentrations (ng/g lipid) of D4 were greatest in herring (18.4) and cod (17.5), and lowest in shrimp (5.9). For D5 and D6, the concentrations were greatest in herring (respectively 1881 and 26.6), intermediate in cod (respectively 356 and 14.7), and lowest in shrimp (respectively 80 and 2.9). Generally, geometric mean concentrations of cVMS in biota decreased over the first four years and, except for D5, were approaching or were less than the analytical detection limits in the 2014 samples, especially for shrimp. Time trend analysis following OSPAR guidelines (OSPAR 2008) requires five years of data. When applied to the first four years, trend analysis using these guidelines detected no significant trends for D5 in biota or sediment. However, marginally significant decrease (p=0.077) was observed for lipid normalized concentrations of D5 in cod. When using ANOVA, a significant decrease was detected for D4 and D5 in cod, but not for D6. There was high variation in lipid content of cod within and between years. The lipid content of whole cod was reduced by at least 50 percent from 2011 to 2013, and then showed a slight increase in 2014. Thus, a mixed effect model combining whole body lipid content (within years), as well as a between-year effect on lipid-normalized D5 concentrations, demonstrated significant year effect. Similar to that observed for cod, lipid-normalized concentrations of D5 in herring were lowest in 2014, compared to 2011-2013. Herring had higher lipid content and higher concentrations of cVMS than cod. A mixed effect model with whole body lipid fraction versus lipid-normalized D5 concentrations also demonstrated significant year effect for herring. Based on OSPAR guidelines, no significant trend was detected between years for concentration (w.w.) of D5 in the 0-1 cm sediment.

WE202
IFRA ENVIRONMENTAL STANDARDS: RISK AND HAZARD ASSESSMENT UPDATE FOR 2016
A. Lapczynski, RIFM / Environmental Specialist; D.T. Salvito, Research Institute for Fragrance Materials (RIFM) / Dept of Environmental Science; M. Vey, C. González, IFRA
To assure safety of fragrance ingredients in consumer products, International Fragrance Association expanded the fragrance industry's self-regulatory safety program with the development of IFRA Environmental Standards for both risk and hazard in 2008. Fragrance material risk assessments for these Standards are incorporated in the Research Institute for Fragrance Materials' (RIFM) testing program in coordination with its Expert Panel. To identify materials for risk assessment refinement, fragrance materials were screened using the RIFM Environmental framework and 2008 IFRA volume of use survey as reported for both Europe and North America. The Framework for this evaluation was published in Environment Toxicology and Chemistry (Salvito et al., 2002, 1301-1308). In addition, hazard assessment on these materials was also performed and reviewed. As a result nearly 3,000 materials were screened with preliminary risk quotients estimated to rank priority materials for risk assessment refinement. In an effort to provide greater transparency to the IFRA Environmental Standards, RIFM reports the most recent results of these additional tests (for both risk and hazard assessments) at both the annual SETAC NA and Europe meetings. These studies include persistence testing (ready biodegradation tests and die-away

studies), bioaccumulation, and acute and chronic aquatic toxicity. Incorporating these new data in a second tier risk and hazard assessment for these materials will also be presented.

WE203

Comprehensive review of several surfactants in the marine environment: fate and toxicity

M. Jackson, Shell Health / Shell Health Risk Science Team; C.V. Eadsforth, Shell International / Shell Health; D. Schowanek, Procter & Gamble / Brussels Innovation Center; T. Delfosse, The Procter & Gamble Company / Product Safety Regulatory Affairs; A. Riddle, Ecospan; N. Budgen, AstraZeneca

Numerous environmental risk assessments of surfactants in the freshwater compartment have been developed (HPV, i.e. HERA, OECD REACh, etc), which can serve as a basis for the marine compartment through extrapolation of freshwater data to marine data. However, risk assessment of surfactants in the marine environment, based upon experimental marine data has hardly been investigated. To investigate the extent and quality of available data from marine studies (water and sediment), ERASM (Environmental Risk ASsessment and Management) commissioned a compilation of marine exposure and effects data for a number of current and historical surfactants (alcohol ethoxylates (AE), alkyl sulphates (AS), alcohol ethoxysulphates (AES), linear alkylbenzene sulfonates (LAS), and ditallow dimethyl ammonium chloride (DTDMAC)). Industry sources and the literature identified, evaluated and reported a variety of biodegradation and ecotoxicological studies. Marine biodegradation studies reported half lives in the range of 2-28 days (AE), 0.3-20 days (AS), 1-50 days (AES), and 0.3-45 days (LAS) (no biodegradation studies were found for DTDMAC). A wide variation in the number of published marine ecotoxicological studies was found for each of the surfactant classes. AS and LAS have been studied most, and AE, AES and DTDMAC the least. Marine invertebrates are the most studied class of organism in both acute and chronic toxicological assessments, whereas plants and fish are comparatively much less studied, particularly in terms of chronic assessments. Based on data ranges and mean toxicities from the studies reviewed, it was concluded that the toxicity of the five surfactants, from highest to lowest is: LAS > AS > AE > DTDMAC > AES. Acute toxicity (for algae, invertebrates and fish) was shown to be generally equisensitive across the board. Where it was possible to compare marine and freshwater ecotoxicological values, marine data ranges generally fell within typical freshwater data ranges. Marine bioconcentration data are virtually non-existent, and were only available for LAS and AS. Significant gaps in data were found in the marine ecotoxicology assessments for all surfactant classes.

WE204

Fate and effect of sediment-associated triclosan in a freshwater microcosm setup: the relative importance of bioaccumulation and biotransformation

R. Windfeld, Roskilde University / ENSPAC; I. Roessink, Alterra / ERA team; P. van den Brink, Alterra and Wageningen University / Aquatic Ecology and Water Quality Management Group; D.T. Salvito, Research Institute for Fragrance Materials (RIFM) / Dept of Environmental Science; H. Selck, Roskilde University / Dept Environmental Social and Spatial Change

Aquatic environments are increasingly exposed to household and personal care products (HPCs) from their extensive use in urbanized areas. The environmental fate of these chemicals and their impact on benthic communities in receiving waters is not completely understood. This study aims to examine the fate of sediment-associated triclosan (TCS) as well as its toxic impact on the benthic community in a fresh water microcosm system. To investigate toxicity of TCS, a community of benthic invertebrates was exposed for 60 days to a high and a low concentration of TCS. The community consisted of a range of organisms; *Gammarus pulex, Tubifex tubifex, Lumbriculus variegatus, Asellus aquaticus* and *Caenis horaria*. The impact on the community was recorded as decreasing organism abundance. Benthic systems containing *T. tubifex* and *G. pulex* were employed to examine the fate of TCS during 30 and 60 days, respectively. The biotransformation capacity of these organisms was assessed by measuring the concentration of TCS and selected metabolites in overlying water, sediment and organism tissue after the two exposure intervals, respectively. The results will be discussed in the context of how bioaccumulation and biotransformation of the products will affect the environmental fate of these compounds

WE205

LogP: a classic endpoint for ERA, but what happens when the main part of the test substance is a resin-like insoluble, volatile, mostly solid, complex mixture and constituents are unknown?

B. CASENAVE, CEHTRA SAS; S. LEGAY, FCBA; R. SAMSERA, CEHTRA SAS; P. Thomas, CEHTRA SAS / Ecotoxicology and Risk Assessment

Under the REACH review program several kinds of substances are considered: monoconstituents, multiconstituents & UVCBs. Across these substance types several families always present a challenge to test especially in physico-chemistry, ecotoxicology and environment. One of these challenging groups is fragrances. \n Fragrance chemicals fall under multiple categories, they can be natural, synthetic, monoconstituent, multiconstituent or considered as UVCBs. One group of fragrances that falls under the title of multiconstituent/UVCB are known to be most difficult to assess: Essential oils. Essential oils (EO) are complex mixtures, with differing but often low solubility, high volatility and are known to contain some toxic constituents such as terpenes. Some of these substances are even more complex: gums, resinoids and concretes, extract from natural raw material like essential oils. They are as complex as EO but their composition is mostly unknown and their physical state leads to further difficulties for physico-chemical and ecotoxicity testing: they are (mostly) solid(ish), extremely viscous resins, with a frozen honey-like texture. However, some of these substances still require environmental risk assessment under the registration process. Therefore some key PhysicoChemical endpoints are needed, such as water solubility and/or LogP values. It is difficult to determine the LogP value of a substance which is solid(ish) with a composition which is basically unknown except for the fact that the number of constituents amounts to potentially well over a hundred. We discuss the protocol we designed to meet the requirements of the log Kow endpoint following the OECD 123 (Slow Stir & HPLC) guideline for one of these substances and how we expect to use this result in the REACH Chemical Safety Report. Keywords : risk, assessment, logP, fragrance

WE206

Ecotoxicity of natural complex mixtures: raw material of plant extracts which are resin-like solids.

R. SAMSERA, CEHTRA SAS; N. DELPIT, Laboratoires des Pyrénées et des Landes; P. Thomas, CEHTRA SAS

Under REACH review program several kinds of substances are considered: monoconstituents, multiconstituents, & UVCBs. Across these substance types several families always present a challenge to test especially in ecotoxicology and environment. One of these challenging groups is fragrances. \n Fragrance chemicals fall under multiple categories, they can be natural, synthetic, monoconstituent, multiconstituent or considered as UVCBs. One group of fragrances that falls under the title of multiconstituent/UVCB are known to be most difficult to assess: Essential oils. Essential oils (EO) are complex mixtures, with differing but often low solubility, high volatility and are known to contain some toxic constituents such as terpenes. Some of these substances are even more complex: gums, resinoids and concretes, sub-categories of essential oils. They are as complex as EO but their composition is mostly unknown and their physical state leads to further difficulties for ecotoxicity testing: they are (mostly) solid(ish), extremely viscous resins, with a frozen honey-like texture. In order to acquire the data required for registration of these substances, we performed a series of OECD 202 (daphnid acute studies) using WAF methodology, with a protocol adapted to fit the substances in question, taking into account the particular properties of these substances in an attempt to keep the results robust from a regulatory point of view. We present and discuss these results on their ecotoxicity properties and the conclusion that we can draw from such results. Keywords: fragrance, raw, material, ecotoxicity

WE207

A thermodynamically-based step by step calculation method to assess aquatic toxicity of mixtures

P. Bicherel, P. Thomas, KREATiS

From an environmental perspective chemical substances do not act in the same way as pure substances tested in the lab. Many substances, classified as such under REACH are actually mixtures (i.e. Natural Complex Substances, such as essential oils). Therefore this is a need to understand mixture toxicity and since water is the universal solvent in the environment, aquatic toxicity of mixtures has been of high concern for many years. One recognised way to obtain toxicity data on mixtures was to follow OECD (2000) Guidance No. 23 on difficult substances and mixtures which advocates use of the water-accommodated fraction (WAF) method (i.e. testing the constituents together at specific loading concentrations). Implementation of the WAF method costs time and money. More recently, research has been conducted in order to determine if an additivity approach can be used to predict aquatic toxicity of mixtures of chemicals or whether independent action predominates. Nowadays the favoured hypothesis is the Concentration Addition (CA) where toxic units of mixture constituents with same toxic mode of action can be summed (Loewe and Muischnek, 1926; Backhaus *et al*., 2003). In this work, the chemical activity concept has been used to normalise the relative part of toxicity of each constituent (Mackay *et al*., 2009; Thomas *et al*., 2015). Schmidt *et al*. (2013) and Smith *et al*. (2013) have both shown that aquatic and terrestrial ecotoxicity can be determined by using summing constituent activities of sub-lethal levels of constituents in a mixture comprised of solid PAHs. However unlike solids compounds (Banerjee *et al*., 1984), liquids partition into each other thus reducing the overall toxicity of the mixture. Therefore the initial rule of CA modified according to the chemical activity has also to be completed by an additional step where the non-bioavailability phase is remove from the calculation. Based on thermodynamic liquid-liquid equilibrium, aquatic toxicity can finally be accurately calculated for mixtures of liquid hydrophobic compounds, like essential oils. This method can provide results within a factor of 2 of experimental results while the CLP additivity method results are at least a factor of 10 lower.

WE208

Predictive laboratory methodology to assess coral bleaching: application to UV filters

J. Fel, LOréal Research & Innovation, Aulnay-sous-Bois, France / Environmental Research; M. Leonard, lOREAL SA

Increasing ocean temperature and acidification, overfishing, coastal development and pollution are well known stressors on coral reefs. They may induce coral bleaching, a process by which corals lose their symbiotic microalgae (zooxanthellae). Ultimately, corals may die when these stressful environmental conditions last too long. Weakened corals, more susceptible to infectious diseases, show poor resilience from episodic bleaching events. Some studies have reported that certain UV filters (mostly 4-methylbenzylidene-camphor, benzophenones and octylmethoxycinnamate) contained in sunscreens lotions and washed off by swimmers, could contribute to coral bleaching. Media took it for granted and suspicion has been extended to all organic UV filters present in sunscreens products. The present study was aimed at clarifying the potential effect that organic UV filters (such as Avobenzone, Octocrylene, Terephtalylidene-dicamphor sulfonic acid, Silatrizole, etc…) may have on different coral species. Two herbicides (Monuron and Diuron) were used as positive references. First a preliminary laboratory screening test was developed to assess potential adverse effect of short exposure (48h) to elevated concentrations (from 1 to 100 mg/L) of the compounds. As a sublethal endpoint predictive of coral bleaching, chlorophyll photosynthetic efficiency of the symbiotic micro-algae (zooxanthellae) was monitored with PAM (Pulse Amplitude Modulated) fluorimetry on nubbins of hard coral species *Seriatopora caliendrum* and *Styllophora pistillata* In a second step, coral nubbins of *Styllophora pistillata* (hard coral) and *Turbinaria reniformis* (soft coral) were exposed for 5 weeks at lower concentrations in 15 liters aquariums, under semi static conditions with weekly solution renewal. A specific analytical methodology was developed, combining automated solid phase extraction with UPLC-UV detection, to monitor the compounds concentrations in sea water and analyze large number of samples. 5 weeks of chronic exposure to these UV filters at concentrations above those reported in natural sea waters, did not induce coral bleaching nor reduce the photosynthetic efficiency of the symbiotic micro-algae.

WE209

iSTREEM 2.0: new enhancements for down-the-drain modeling to support environmental aquatic exposure assessments for cosmetics and personal care products

R. Vamshi, K.E. Kapo, M.L. Sebasky, C.M. Holmes, Waterborne Environmental, Inc.; P. DeLeo, D. Ferrer, American Cleaning Institute

The iSTREEM® model ("in-stream exposure model"), a free and publically-available web-based model supported by the American Cleaning Institute (istreem.org), provides a means to estimate chemical concentrations in effluent, receiving waters, and drinking water intakes (DWI) across the conterminous U.S. as well a number of watersheds in Canada under mean annual and low-flow (7Q10) conditions. This presentation will discuss recent upgrades made to enhance the model, underlying data, algorithms and presentation of results in the new version. iSTREEM® 2.0 incorporates geographic locations of over 12,000 wastewater treatment plant (WWTP) facilities along more than 300,000 segments of effluent-impacted river reaches, providing a framework to integrate geographic data to assess environmental risk for multiple scenarios of interest. WWTP facilities and associated facility level information were derived from the latest available USEPA Clean Watershed Needs Surveys. The river network used by iSTREEM® 2.0 was upgraded to a higher-resolution hydrologic dataset based on the USGS/USEPA NHDPlus version 2, which includes estimated mean annual and low flow (7Q10) data based on USGS stream gage measurements. Model results are presented in a standardized manner for consistent results communication across all users and are provided in a readily usable format (MS Excel) for easy interpretation and further customization of result presentation. Major assumptions used in constructing the model will be discussed. Recent developments are geared to expand adoption of the model by a wide variety of users as an environmental risk assessment tool across multiple commodity groups (cosmetics, personal care products, pharmaceuticals, food additives, pesticides, etc.) that require internal or regulatory environmental assessments. The discussion will also include a comparison of model results between the prior version of iSTREEM® and latest iSTREEM® 2.0 to examine the impact of recent upgrades on the national distribution of predicted environmental concentrations.

Endocrine Disruptors: Exposure, Hazard & Risk Assessment (P)

WE210

Is nitrate an endocrine active compound in fish?

M.P. Mose, University of Southern Denmark / Depertment of Biology; K. Kinnberg, P. Bjerregaard, H. Holbech, University of Southern Denmark / Department of Biology

Nitrate and nitrite taken up into fish may be reduced to NO which is known to be a signalling compound in the organism contributing to the regulation of i.e. steroid synthesis. Exposure of male rats to nitrate and nitrite results in reduced plasma concentrations of testosterone (also nitrate concentrations around or below the limits for drinking water). Nitrate concentrations in streams may be elevated due to releases from agricultural practices. The effects of nitrate and nitrite on endocrine relevant endpoints were investigated in zebrafish (*Danio rerio*) and brown trout (*Salmo trutta*). Zebrafish were exposed to nitrate and nitrite from hatch to sexual maturation (60 d) and sex ratio and vitellogenin concentrations were determined. Juvenile brown trout were exposed in a short-term experiment and the concentrations of vitellogenin were determined. The sex ratio in zebrafish was not affected by exposure to environmentally realistic concentrations of nitrate and nitrite but vitellogenin concentrations were slightly elevated in all of the exposed groups compared to the control; no obvious concentration-response relationship was observed. The outcome of the brown trout experiment is awaiting the final analyses.

WE211

Neuro-endocrine disruption in molluscs - Effects of pharmaceuticals on a serotonin- and dopamine dependent system

H. Holbech, L.B. Sanderhoff, S.P. Waller, K. Pedersen, University of Southern Denmark / Department of Biology

The Mollusca phylum is the second largest animal phylum with around 85,000 registered mollusc species and increasing attention to effects of chemicals on the molluscan endocrine system have been given during the last years. This includes initiation of the development of OECD test guidelines (TG) to assess the effect of chemicals in molluscs. To date no endocrine specific mollusc biomarkers have though been validated and included in draft test guidelines due to lack of knowledge of the endocrine system. Here we investigate effects of pharmaceuticals targeting serotonin and dopamine in a cost efficient and fast *in vivo* system using embryos of the freshwater pulmonate gastropod *Lymnaea stagnalis* (the great pond snail). It is known that serotonin and dopamine are involved in many reproductive processes in molluscs Incl. egg maturation and spawning and that pedal ciliary activity causing *L. stagnalis* embryos to rotate in the eggs is serotonin/dopamine regulated. We have developed a system to quantify embryo rotation and present results of exposure to serotonin, dopamine and different anti-depressive pharmaceuticals (e.g. selective serotonin reuptake inhibitors, SSRI´s) using the *L. stagnalis* embryo rotation test system.

WE212

In silico Screening for Potential Endocrine Disruptors

R. Kühne, N. Ost, Helmholtz Centre for Environmental Research UFZ / Department of Ecological Chemistry; L.A. Baumann, University of Bern / Centre for Fish an Wildlife Health; H. Segner, University of Bern / Centre for Fish and Wildlife Health; J. Arning, German Federal Environment Agency UBA / Section IV   Chemicals; G. Schüürmann, Helmholtz centre for environmental research - UFZ / Department of Ecological Chemistry

Endocrine disrupting activities of chemicals trigger adverse effects on organisms. Endocrine disrupters are suspected to be responsible for a number of diseases as testis and breast cancer, oligospermia of young men, or adiposis. Compounds with endocrine activity are labelled as substances of very high concern (SVHC) and are subject of regulations as e.g. under REACH. However, there are so far no internationally harmonised criteria to identify endocrine active chemicals. Furthermore, the endocrine system is rather diverse. Despite of several already developed OECD tests to reveal respective activities, it is still not clear whether they comprise all (eco)toxicologically relevant pathways. Even more, these tests are rather expensive with respect to costs and duration. Consequently, the number of existing data is limited. In silico tools are promising alternatives to avoid testing or at least to allow for the prioritisation of tests by screening larger compound lists. The German Federal Environment Agency holds a prototype of a structural alert model and corresponding software tool for this task. Based on it, the current study aims to significantly extend this model and to make it available as an automated tool in the software system ChemProp (UFZ Department of Ecological Chemistry 2015. ChemProp 6.3. http://www.ufz.de/index.php?en=6738). The envisaged model will provide a decision tree to identify potential endocrine disruptors and their respective modes of action. The paper gives an overview of the approach and reports results for several modes of action with respect to thyroid hormones. Structural rules to identify potential agonists and antagonists for effects on the ligand bonding domain (LBD) as well as for potential antagonists against the activation factor 2 (AF-2) have been established. Furthermore, the opportunity to derive specific rules for enzyme/protein interaction, thyroid receptor interaction, aryl-hydrocarbon-receptor interaction, and other modes of action based on existing data and mechanistic knowledge has been explored. *Acknowledgment:* This study is financially supported by the German Federal Environment Agency, FKZ 3714 63 412 0.

WE213

Evaluation of anthropogenic micropollutants in drinking water: the Tox-Box approach

A. Eckhardt, German Environment Agency / Toxicology of Drinking Water and Swimming Pool Water; M. Kramer, Rheinenergie; W. Brack, Helmholtz Centre

for Environmental Research UFZ / EffectDirected Analysis; E. Rabbow, German Aerospace Centre; M. Knauer, Hydrotox GmbH; H. Glatte, German Institute for Nutrition; C. Baumstark-Kahn, German Aerospace Center; E. Küster, Helmholtz Centre for Environmental Research, Dept.Bioanalytical Ecotoxicology / Bioanalytical Ecotoxicology; T. Grummt, Federal Environment Agency / Toxicology of Drinking Water and Swimming Pool Water; T. Braunbeck, University of Heidelberg / Centre for Organismal Studies; P. Waldmann, Incosboté; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis

Anthropogenic micropollutants in drinking water have been a concern for several years now. Due to analytical improvements more substances are found in drinking water and their presence has to be evaluated to provide the public with save drinking water. So far only lengthy test protocols mostly in animals are used. The aim of the joint project Tox-Box is therefore the establishment of a test battery that allows for the evaluation of a substance in terms of possible genotoxicity, neurotoxicity and endocrine disruptive effects using in vitro approaches wherever applicable. Based on the theoretical concept of the Health Related Indicator Value (HRIV), published by the German Federal Environment Agency (Umweltbundesamt, UBA) in 2003 a practical approach was designed. For each toxicological endpoint several tests were chosen, which provide for a fast and reliable risk assessment, once a chemical is found. The test battery for genotoxicity will encompass the Umu test, in addition to Ames test and micronucleus test. The assessment of neurotoxicity will consist of testing for necrosis, apoptosis and oxidative stress by comparing neural cells with liver cells as well as assays specific for neurons like neurite outgrowth and MAP kinases. Moreover, the activity of acetyl choline esterase and the development of lateral line organs in zebra fish (*Danio rerio*) will be tested. A third set of tests deals with endocrine effects. These are assessed by applying hormone specific reporter gene assays in combination with the H295R assay. When one of these tests is positive, a reproduction assay in *Potamopyrgus antipodarum* snails will be performed for further clarification. During the project some 60 chemicals were tested by the different project partners. The test scheme which was developed suggests that it will meet the demands for fast and reliable assessment. It will also be in line with the Tox21 program which aims for an increase in *in vitro* testing. From a regulatory perspective, genotoxicity is considered the most relevant endpoint. Since genotoxic effects currently result in the lowest cut-off value, no further testing is required, once a substance is considered genotoxic. When no genotoxic effects can be found the assays for neurotoxic and endocrine effects will be carried out. The guideline for testing will be published as a handbook, first in German. An English version is planned for the near future.

WE214

Investigation of (anti)estrogenicity of triclosan using in vitro and in vivo zebrafish bioassays

H. Serra, University of Bordeaux / Ecoloxicology unit; F. Brion, INERIS / Ecotoxicology Unit; H. Budzinski, University of Bordeaux / UMR EPOC LPTC; S. Ait-Aissa, INERIS / Ecotoxicology Unit

Triclosan (TCS) is a wide spectrum antimicrobial agent used in many personal care products (PCPs) that has been detected in surface water and biota. TCS is suspected to be an endocrine disrupting chemical (EDC) and to interact with the estrogen and androgen signaling pathways. However, data available regarding its estrogenic or anti-estrogenic potency provide contradictory information, highlighting the uncertainty regarding its endocrine disruptive potential. The few studies published so far on chronic reproductive effects of TCS on fish report ambiguous results, i.e. a male bias sex ratio in Japanese medaka but a vitellogenin induction in male mosquito fish. In this context, our study aimed to investigate whether TCS acts as an agonist or an antagonist of the estrogen receptor (ER) in human (*in vitro*) and in zebrafish (*in vitro* and *in vivo*). For this purpose, we assessed luciferase-dependent ER transactivation *in vitro* using a human breast cancer reporter cell line expressing hERα (MELN cells), and three zebrafish (zf) liver cell lines (ZELH) stably transfected with zfER (i.e. ZELH-zfERα, -zfERß1 and -zfERß2). In addition, *cyp19a1b* gene induction, which is strictly ER-regulated, was assessed in transgenic *cyp19a1b-GFP* zebrafish embryos (EASZY assay). Our results showed that TCS alone from 3nM to 10μM was unable to induce luciferase activity whatever the *in vitro* models used. At higher concentrations, cytotoxic effects were observed. Co-exposure of cells with E2 0.1nM (ZELH-zfERß1, ZELH-zfERß2 and MELN) or E2 3nM (ZELH-zfERα) and increasing concentrations of TCS had no effect on the E2-induced luciferase activity in either human or zebrafish cells, suggesting that TCS did not elicit any antagonist activity. *In vivo*, TCS alone did not induce GFP in transgenic zebrafish embryos, but decreased the basal *cyp19a1b* expression at 1μM. This effect could reflect the developmental toxicity of TCS as revealed by lethargy and swimming alteration observed in exposed-fish at 1μM. Co-exposure with TCS 1μM and E2 resulted in ambiguous responses: TCS 1μM decreased E2-induced *cyp19a1b* expression by 24% as compared to E2 10nM alone, whereas it slightly increased E2-induced *cyp19a1b* expression at 0.625 nM. All together, our data indicate that TCS does not alter the ER signaling *in vitro* in either human and zebrafish cell lines but seems to alter the E2-induced response *in vivo* through unknown mechanisms.

WE215

Development of a zebrafish embryo test for environmental risk assessment of pharmaceuticals with endocrine disrupting properties

E.D. Michiels, L. Vergauwen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences; S. Van Cruchten, University of Antwerp / Department of Veterinary Sciences; D. Knapen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences

Pharmaceutical companies are obligated to perform an environmental risk assessment for each new drug that is launched on the market. The mandatory tests for potential endocrine disrupting (ED) compounds require a lot of test animals, which is not consistent with the 3R principle. Therefore, the aim of this study is to develop a zebrafish embryo test, which is not considered an animal test according to the European regulation on the use of laboratory animals, and which is capable of detecting and discriminating among 5 endocrine disrupting modes of action (MOAs). The MOAs that will be studied are aromatase inhibition, estrogen receptor (ER) agonism and antagonism, androgen receptor (AR) agonism and antagonism. As a first stage of test development, 1 pharmaceutical per MOA was investigated to map differences among the 5 compounds in zebrafish embryos at the morphological, physiological and molecular level. We are currently exposing transgenic zebrafish embryos of 2 lines to aid in discriminating among the MOAs: *SR4G* (fluorescent signal after glucocorticoid receptor activation) and *5xERE:GFP* (reports estrogen receptor activation). An ontogeny study is ongoing to determine the gene transcription levels of the receptors, biomarkers and enzymes of the steriodogenesis pathway which will be compared to the gene transcription levels of embryos which were exposed to each of the 5 pharmaceuticals. As a model for ER agonism, 17α-ethinylestradiol (EE2) was used. Fulvestrant was used to investigate ER antagonism. 17β-trenbolone and flutamide were respectively the AR agonist and antagonist. Letrozole was used as a model for aromatase inhibition. Both receptor agonists showed some sublethal effects, while no sublethal effects were observed after exposure to flutamide. After EE2 exposure, the embryos showed sublethal, dose-dependent skeletal malformations of the spine. Cranial malformations were only significant around the LC_{50} concentration and above. For 17β-trenbolone heart rate and growth were already significantly decreased at sublethal concentrations. Swim bladder inflation and swimming behaviour were impaired for both agonists at sublethal concentrations. The data available from 5 medicines with 5 different ED MOAs show the potential of a combination of different datatypes to distinguish among the 5 MOAs. In order to establish a consistent profile that can be used for ED screening of medicines, additional compounds will be tested.

WE216

CYTOCHROME P450 AS POTENTIAL TARGET FOR ENDOCRINE DISRUPTION IN TILAPIAS CAGED IN FOUR RESERVOIRS OF IGUAÇU RIVER

F. Yamamoto, Universidade Federal do Paraná / Cell Biology; G. Diamante, University of California, Riverside / Environmental Toxicology; R. Bombardelli, Universidade Estadual do Oeste do Paraná; D. Schlenk, University of California-Riverside / Department of Environmental Sciences; C.d. Oliveira Ribeiro, Universidade Federal do Paraná / Department of Cellular Biology

Environmental chemicals originating from human activities may enter aquatic environments and interfere with the endocrine system of biota. The aim of this work was to investigate endocrine effects in male tilapia (*Oreochromis niloticus*) caged in four cascating reservoirs of the Iguaçu River. RT-qPCR analysis revealed different transcript levels of cytochrome P450s (CYPs) in liver, brain and gonads between the four groups and control fish maintained in the laboratory. Expression of *cyp1a* and *cyp19* aromatase in liver and brain, respectively, was higher in tilapias from the Salto Caxias (SC) reservoir than laboratory controls, but *cyp3a* in the gonads of these individuals was downregulated. In tilapia from Salto Santiago (SS) reservoir, *cyp3a* in liver and *cyp19* in gonads was up and downregulated, respectively. Despite no differences in vitellogenin expression and CYP19 activity, CYP3A activity (testosterone hydroxylase) in liver was inhibited in tilapia from all four reservoirs when compared to the control group. The results obtained in this study indicate that CYPs 450 represents a potential target for chemicals available in the four reservoirs. Since CYPs have many roles, such as biotransformation of xenobiotics and steroids, normal biosynthesis and clearance may be compromised in fish exposed to the water from Iguaçu River.

WE217

Butyltin levels and imposex occurrence in Hexaplex trunculus (Gastropoda, Muricidae) from the Northern Adriatic Sea (Italy) after the EU ban

F. Cacciatore, ISPRA-Institute for Environmental Protection and Research / Mitigation and Prevention of Impacts; S. Noventa, C. Antonini, M. Formalewicz, C. Gion, R. Boscolo Brusà, D. Berto, M. Gabellini, ISPRA - Institute for Environmental Protection and Research; M.G. Marin, University of Padua / Department of Biology

Imposex (the development of additional male sex organs in females Caenogastropods) is an endocrine disruption effect commonly used to indirectly assess the presence of tributyltin (TBT), a compound used worldwide in industrial and agricultural applications, mostly in antifouling paints, and now ubiquitous in the marine and transitional environments. Organotins were banned in the

European Union by the EC Regulation 782/2003 and TBT compounds are among the priority hazardous substances according to the European Water Framework Directive 2000/60/EC and its daughter Directive 2008/105/EC. This study aims to assess the butyltin (BT) content in *Hexaplex trunculus* from the Venice Lagoon and the Northern Adriatic Sea after the EU ban. In 2013-2015, gastropods were collected in five stations (2 in the Venice Lagoon, 3 in the Adriatic Sea) in order to assess their BT (TBT, DBT, MBT) contamination and imposex levels. The stations were chosen among those previously surveyed in the same area, for a temporal comparison. Very low BT concentrations (range ΣBT: 16-29 ng cation/g d.w.) and imposex levels (range %I: 5-38%; VDSI < 3.3; RPSI < 0.10%) were found, with a clear decline respect to previous studies in the same area. Quite similar values were shown in lagoon and off-shore samples. TBT levels and VDSI values determined in this study are consistent with those reported in literature for the same species from other geographical areas, with VDS< 3 at TBT concentrations of 15 ng/g d.w.. However, contrary to previous surveys in the Venice Lagoon, imposex indices and female penis lengths did not correlate with BT body burden in females. This finding could be explained by the high sensitiveness of the species that is known to show an initiation of imposex at concentrations lower than 1 ng Sn/g d.w. (2.44 ngTBT/g). Moreover, also the development of imposex exhibited a different course respect to that observed before TBT ban, when BT concentrations and imposex levels were higher. Previous studies documented first the development of the incipient penis, followed by the development of vas deferens. In this study, the onset of imposex occurred first with the appearance of the vas deferens and then with the development of the incipient penis. In this regard, it cannot be excluded that other factors may alter the endocrine control of imposex development, such as exposure to heavy metals, changes in environmental conditions and the influence of other endocrine disrupting chemicals.

WE218
An integrative study design for a zebrafish full life cycle toxicity test
E.R. Salinas, BASF SE / Experimental Ecotoxicology; M. Braun, BASF SE; L. Weltje, BASF SE / Crop Protection   Ecotoxicology; M. Bergtold, BASF SE
Fish full life cycle (FFLC) toxicity tests are considered to provide definitive assessments for population relevant endpoints, including those mediated by endocrine mechanisms (i.e. OECD Conceptual Framework level 5). These tests have been conducted with various fish species possessing diverse life history traits, often as part of a global registration package for plant protection product active substances. A life cycle test protocol with limited validation (OECD TG 240) exists for the medaka (*Oryzias latipes*), but other species such as the zebrafish (*Danio rerio*) are more commonly used for toxicity testing and research. In recent years, several fish test guidelines have been released, which are targeted to screen for endocrine effects on specific stages of the fish life cycle and have been robustly validated using zebrafish. Herein we describe a study design for a zebrafish full life cycle toxicity test that integrates critical aspects from previously validated guidelines. The exposure starts with freshly fertilized eggs (F0-generation) from a non-exposed population. The effect of the test substance on the survival, growth, and sexual development of the F0-generation are evaluated (consistent with OECD TGs 210 and 234). After the onset of consistent spawning behavior (approx. 70 days post hatching), reproduction is assessed as fecundity and fertility (consistent with OECD TG 229). Upon sacrifice, the phenotypic sex of adult F0 fish is confirmed and biomarkers such as vitellogenin can be measured (consistent with OECD TG 229 and 234). Fertilized eggs produced by the F0 test groups are used to start the F1-generation, which is exposed for about 34 days (until approximately 30 days post hatch), to evaluate effects on hatchability, development, survival and growth of the F1 early life stages (consistent with OECD TG 210). We present data demonstrating successful zebrafish growth, sexual development and reproductive performance and provide a statistical power analysis for apical population relevant endpoints.

WE219
A multi-generation study on the effects of 17β-dihydroequilin, E1 and E2 in the medaka (Oryzias latipes) following a combined protocol based on the OECD 229 and OECD 234 Guidelines
L.A. Constantine, Pfizer, Inc. / Pharmacokinetics Dynamics and Metabolism
Two separate studies were conducted to understand the endocrine effects of 17β-estradiol and Conjugated Estrogens (CE), specifically, estrone (E1) and dihydroequilin (DHE) on three generations of Japanese medaka. In the multigeneration life-cycle test, medaka were exposed to nominal concentrations of 1.0, 7.5 and 75 ng a.i./L each of E1 and DHE, for total exposure of 2.0, 15 and 150 ng a.i./L in combination, a positive control of 100 ng a.i./L E2 and a negative control. Two additional dosing groups were exposed; one to 1.0 ng a.i./L E1 alone and the other to 1.0 ng a.i./L DHE alone. Following a pre-exposure period of 26 days to identify actively spawning fish, spawning groups of 5 males and 5 females were formed and exposed for 21 days under flow-through conditions to evaluate reproduction of the parental generation (F0) as per OECD 229, Fish Short Term Reproduction Assay (FSTRA). Following the FSTRA, an evaluation of sexual development in the F1 generation using eggs from the F0 generation carried through 83 days post hatch (dph) was conducted as per OECD 234, Fish Sexual Development Test (FSDT). Following the 83 day exposure of the F1 generation, most of the treatment groups were terminated in keeping with the FSDT. However, exposures in the 2.0 and 15.0 ng a.i./L E1/DHE combination doses, as well as the negative control were continued through reproduction (22 days) and hatching of the F2 generation embryos (4 dph). A similar study was conducted to evaluate 17β- estradiol at nominal concentrations of 2.75, 8.8, 28.2 and 90.1 ng/L. Survival, growth, reproduction (fecundity and fertility), hatching success, sex ratio and VTG data will be presented for these three endocrine disrupting compounds.

WE220
Is the fungicide tebuconazole toxic for the reproduction of aquatic invertebrates?
K. Heye, Goethe University Frankfurt/ Main / Aquatic Toxicology; I. Stahlhacke, M. Oetken, J. Oehlmann, Goethe University Frankfurt / Aquatic Ecotoxicology
The triazole fungicide tebuconazole acts via an inhibition of the ergosterol synthesis of fungi, but it is also suspected to interfere with the steroidogenesis pathway. In rats, tebuconazole impairs reproduction by an interference with the endocrine system. Whether tebuconazole shows similar effects in invertebrates is unknown, even though for some invertebrate species effects of endocrine disrupting chemicals have been described. As tebuconazole occurs in surface waters at concentrations up to 590 ng/L (Hesse, Germany), the fungicide may interfere with the reproduction of aquatic invertebrates and therefore may pose a risk for invertebrate populations. \nIn order to investigate the toxicity of tebuconazole, long-term reproduction tests with the snail *Potamopyrgus antipodarum* (28 days) and the water flea *Daphnia magna* (21 days) were conducted. The number of embryos and the number of offspring served as endpoints for *P. antipodarum* and *D. magna*, respectively. In addition, the formation of male offspring was investigated in *D. magna* as an indicator for endocrine disruption. Other pesticides, mostly insecticides known as juvenile hormone analogs have shown to induce male formation. \nThe results of the ongoing study will be presented and discussed. \nAcknowledgments: This study is funded by the Federal Ministry of Education and Research (BMBF, Germany) within the framework of the project “NiddaMan” (02WRM1367A).

WE221
A preliminary assessment of human health risk due to inhalation of atmospheric POPs in an agricultural area in Turkey
E. Can Güven, Akdeniz University / Department of Environmental Engineering; K. Gedik, Akdeniz University / Dept Environmental Engineering; P. Kurt-Karakus, Bursa Technical University / Environmental Engineering Department
Persistent organic pollutants are a group of chemicals that resist to degradation in the environment, bioaccumulative, have toxic effects and undergo long range atmospheric/aquatic transport. Among these chemicals, there exist commercially produced halogenated chemicals such as polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCPs). These chemicals are of public concern due to their adverse health effects both on humans and wildlife even at very low concentrations. Similar to other regions of the world, OCPs were widely used for agricultural purposes in Turkey. Additionally, even though never produced in Turkey, PCBs were imported for various applications. As the atmospheric transport is main mechanism in the cycling of these chemicals, inhalation is one of the important exposure pathways and health risk assessment is recommended. In this study, atmospheric OCPs and PCBs concentrations were measured by passive sampling in an agricultural region. In addition, the cancer risks for lifetime inhalation of OCPs and PCBs were calculated based on these atmospheric levels. Total OCPs and PCBs concentrations were 266-2374 $pg.m^{-3}$ and 1.40-283 $pg.m^{-3}$, respectively. But one sampling site, the total lifetime cancer risks due to inhalation of OCPs and PCBs were lower than the acceptable risk level of 1×10^{-6} at all sites. Calculations showed that children exposure is about two times higher than adult exposure. Since there are three main exposure pathways namely ingestion, inhalation and dermal absorption, other exposure routes should also be evaluated in order to assess the total risk.

WE222
Air multi-contamination by endocrine disruptors in urban area of Paris (France): characterization by chemical and biological analyses
L. Oziol, University of Paris-Sud / UMR CNRS; E. Guigon-Moreau, UPMC / UMR Metis; M. Teil, EPHE; F. Alliot, EPHE UMR 7619; M. Bimbot, V. Huteau, Univ. Paris-Sud / UMR ESE; Y. Levi, Univ. Paris Sud; M. Chevreuil, EPHE
The continuous contamination of atmosphere by a number of endocrine-disrupting (ED) compounds involves new societal concerns about the importance of human exposure to low dose of compounds in mixture and subsequent effects upon health. Up to now, that question was poorly documented and knowledge improvements are needed about ED compounds transfers in ambient air, both outdoors and indoors, and also, towards humans. In parallel, hazards arising from their intake by the respiratory tract (*via* gaseous or particulate phases) need to be specified. In this context, the multi-contamination of both the two atmospheric phases, gaseous and particulate, was characterized in urban area of Paris (France) by a two-track approach: the determination of the air contamination levels in several ED compounds families (plasticizers, surfactants, dielectrics, flame retardants, and compounds from combustion synthesis), and the evaluation of the

ED potency of the "cocktail" of air contaminants on bioassays integrating interactive effects between compounds. Disruptions of the transcriptional activity depending on nuclear receptors to estrogens, androgens and thyroid hormones were thus studied, since alterations of these endocrine systems were previously reported in animals and humans. In this way, the air contamination from an urban area was compared during contrasted seasons with this from a forest environment and a suburban area, or with this from indoor living places including three different urban habitats (apartment, office, day nursery). All the ED compounds appeared ubiquitous, as well outdoors as indoors. Except PAHs, they showed indoor concentrations 10 to 80 times higher than the indoor ones. In addition, contrary to *a priori* ideas based upon the low vapour pressures of semi-organic volatile compounds, it appears that human exposure *via* the respiratory tract occurs mainly through the gaseous phase, which is supported by the international literature. Theses contamination data associated with the known ED nature of the target compound were in accordance with the relative ED potency of the ambient air between atmospheric phases, seasons or environments, and the nature of the highlighted ED effects: estrogenic, anti-androgenic and thyroid-like. The chronic human exposure to indoor air contamination, namely *via* the gaseous phase, might induce adverse sanitary events related to the ED potency of that contamination.

WE223

Estimating the carcinogenic and non-carcinogenic effects of persistent organic pollutants in food stuffs using risk assessment indices

O. Ogbeide, University of Benin / Environmental Management and Toxicology; I. Tongo, University of Benin / Dept of Animal and Environmental Biology; A.A. Enuneku, University of Benin, Benin City / Dept of Environmental Management and Toxicology; N.O. Erhunmwunse, M. Ainerua, University of Benin, Benin City, Nigeria / Animal and Environmental Biology; E. Ogbomida, National Centre for Energy and Environment / Ecotoxicology and Environmental Forensics; e. ewere, University of Benin Benin City Nigeria / Dept of Animal and Environmental Biology; L.I. Ezemonye, University of Benin / Animal and Environmental Biology

Chemicals play a part in almost all human activities including medicine and agriculture. However, there is a staggering mismanagement of chemicals in Nigeria, leading to high levels of contamination in various environmental matrices and food stuffs. The increasing presence of these chemical residues in various commonly consumed food products is of great concern, due to potential adverse effects on humans and possible impact on sustainable development. In an attempt to estimate the impact of chemicals on human health in Nigeria, several studies have been carried out by researchers at the Laboratory of Ecotoxicology and Environmental Forensics, University of Benin. Pesticides and polycyclic aromatic hydrocarbons (PAH) have been analyzed in food products using gas chromatography (GC) equipped with electron capture detector (ECD), while the attendant health risk associated with the consumption of POPs in contaminated food stuffs have been determined using relevant risk assessment indices for cancer and non-cancer risk. Results have shown high concentrations of these persistent chemicals in several food stuffs in Nigeria, while human health risk predictions has shown that dietary exposures to POPs, increases the potential for cancer and non-cancer effects in humans after consumption. Therefore, there is the need for a concerted effort by relevant authorities in ensuring that chemical use is regulated while the ban on POPs is enforced.

WE224

Consumption of canned foods in Nigeria: assessing the associated human health risk.

L.I. Ezemonye, University of Benin / Animal and Environmental Biology; M. Ainerua, University of Benin, Benin City, Nigeria / Animal and Environmental Biology

Ensuring food safety to protect public health and promote economic development remains a significant challenge in both developing and developed countries. In Nigeria, the changing lifestyle of people has resulted in increased consumption of canned foods which makes it imperative to determine the levels of chemical additives to avert health risks associated with consumption. To this end, levels of food additives (Nitrite and Nitrate, Sodium Chloride) and heavy metals (Fe, Mn, Zn, Cd, Pb, and As) in canned foods frequently consumed in Nigeria, were assessed to estimate human health risks associated with consumption. Chemical additives and Heavy metals were assessed using Perkin-Elmer spectrophotometer and Atomic Absorption Spectrophotometer (AAS) respectively. Human Health Risk estimates were obtained using standard indices (Estimated Daily Intake (EDI), Target Hazard Quotient (THQ), Hazard Index (HI), and Dietary Exposure (DE)). Results showed that the concentrations of Nitrate, Fe and Cd in all the canned food categories exceeded recommended limit set by the European Union, indicating potential health risk. Further risk estimations showed EDI values for Cd in all the canned food categories above the tolerable daily intake, while DE for Fe in canned sweet corn, Fe, Zn and Pb in canned beans/peas had values above recommended limits. THQ values for all the canned foods were less than 1 except canned beans/peas, while HI was above 1 in the canned fish category. This implies that there is risk of non-carcinogenic health effects from the consumption of canned beans/peas. Therefore, it's imperative that there should be constant monitoring of food additives and heavy metals in canned foods.

Pollutant risks to amphibians and reptiles: how much we know and what we need (P)

WE225

Amphibians and Plant-Protection Products - What Research and Action Is Needed?

A. Aldrich, Research Station Agroscope ACW / Ecotoxicology; M. Junghans, Swiss Centre for Applied Ecotoxicology EAWAG - EPF / Ecotox Centre; B. Schmidt, KARCH and University of Zurich / Department of Evolutionary Biology and Environmental Studies

The majority of Swiss amphibians are at risk. There is a large number of factors that are discussed as possible causes, including plant-protection products (PPP), although to date we have not been able to adequately quantify the impact of the latter. Since the influence on amphibian populations of PPP's in the form of active ingredients, wetting agents, breakdown products or mixtures has not yet been studied to any great extent, a workshop was held with over 30 invited experts from authorities, academia, industry, agriculture, environmental NGOs, Swiss amphibian research institutes as well as environmental law. A majority of the participants deemed further research on the influence of plant protection products on amphibians appropriate. Identified research issues were: What is the exposure of amphibians to PPP in natural environments? How great is the risk to which species and developmental stages in what crops from what PPP? What effects on individuals are relevant at the population level? What population models can be used to estimate the effects observed in the laboratory with individuals, at the population level as a whole? What effect do co-formulants have on toxicity? How high is the variability in sensitivity between the various amphibian species and populations? Can entrance criteria be developed in order to identify potentially problematic substances for amphibians for the ecotoxicological risk assessment in the authorisation of PPP's? What risk-management options are there both inside and outside of the field? How relevant are other factors for the decline in the amphibian population, compared to PPP's? A further topic of discussion was how to better protect amphibians from PPP's by reducing their exposure on open ground. Discussed measures were: Avoidance of PPP application during migration in affected areas with the help of prediction models Recommendation for not using specific products Advice and awareness-raising for farmers Advice and awareness-raising for private users in their home gardens Compensation measures (e.g. amphibian-specific ecological compensation areas) Promotion of amphibians via direct payments and/or existing label schemes, e.g. IP-Suisse Reduction of PPP use through alternative plant-protection strategies

WE226

Incorporating Habitat Variables into a Weight-of-Evidence Analysis of Amphibian Risks in Wetlands

R.N. Hull, Intrinsik Environmental Sciences Inc.; D. Hausleietner, Seepanee Ecological Consulting Ltd.; M. Machmer, Pandion Ecological Research Ltd.; L.J. Marshall, Intrinsik Environmental Sciences Inc. / Environmental Scientist; C.E. Moore, Intrinsik Environmental Sciences Inc.; J. Thorley, Poisson Consulting Ltd.

Weight-of-evidence analyses may include a comparison of ambient chemical concentrations in the environment to environmental guidelines, field survey results, and toxicity test results. Risk assessment of amphibians in wetlands can benefit from also considering habitat variables, as these can have a profound influence on populations and communities. The current study compared metal concentrations in water collected from eight wetlands potentially influenced by industrial emissions, and four reference wetlands, to guidelines and amphibian toxicity data collated from the literature. Amphibian diversity and abundance data for these same wetlands also were collected. Statistical analysis of habitat variables relative to amphibian occupancy and relative abundance was completed for these and approximately 40 other wetlands in the area. Including the habitat evaluation contributed to understanding the potential risks to amphibian populations in wetlands near the facility. The analysis showed that, although concentrations in water exceeded guidelines for several metals/metalloids, concentrations generally were below amphibian toxicity effect levels. Habitat variables and life history characteristics of the amphibians were stronger indicators of population presence and abundance than metal concentrations.

WE227

Evaluation of effects of herbicide products and their active substance on amphibian: Tests of glyphosate exposure on the development of common toad (Bufo bufo)

J. Sadowski, F. Göge, JKI; A. Esther, JKI / Vertebrate Research

Common toad (*Bufo bufo*) is a typical species of the European agricultural landscape and potentially threatened by pesticide exposure. Even modern perennial agrochemical use is accompanied by a high exposure risk. However, studies on the influence of pesticide exposure to European amphibian species are rare. For that reason we tested in an acute toxicity study the influence of the herbicide Roundup® PowerFlex and its active ingredient (a.i.) glyphosate in high and environmentally relevant doses on survival and development of Common toad. In the laboratory, eggs were exposed to Roundup® PowerFlex or glyphosate for 24h or to compare with untreated control groups. Rate of hatching individuals and size, weight and survival rate during time to metamorphosis were determined. The preliminary results showed that high dose treatments let to expected severe effects on toad's development. Environmental relevant doses seemed to have no effects, but more replications would be necessary. Systematic toxicity studies are necessary to assess the risk of European amphibian species due to the lack of suitable and comparable data. Standards for laboratory tests should be developed and single and mixed pesticide exposure scenarios on environmentally relevant level should be done for risk assessment of different species living in the current agricultural landscape.

WE228
Cadmium but not Lead affects Xenopus laevis fertilization and embryogenesis.
S. Slaby, Université Lille1 / Biology; S. Lemière, Université de Lille / Laboratoire de Génie Civil et de géo Environnement; A. Lescuyer, J. Bodart, Université de Lille / Unité de Glycobiologie Structurale et Fonctionnelle; A. Lepretre, Université de Lille / Laboratoire de Génie Civil et de géo Environnement; M. Marin, University of Lille1 / Biology
Environmental contaminations have significant effects on biodiversity, especially on Amphibians group. This class, containing the highest number of known threatened species, is highly sensitive towards chemical contaminants. Despite toxicity, dominance and persistence in the environment of metal contaminants, effects on amphibians remain poorly documented, except through the FETAX test. But this assay, use to determine lethal and teratogenic concentrations of solutions, runs with few-days old tadpoles. So effects on gametes, external fertilization and embryogenesis are not considered. Whereas these steps are also exposed to environmental contaminations, they're stills poorly documented yet. In this context and according to previous results of ours showing that *X. laevis* oocytes maturation was altered by metal chlorides, we examined how cadmium and lead interact with earlier stages of *Xenopus laevis*, from fertilization to 8-cells zygotes. While lead doesn't disturb the fertilization rates, cadmium decreases these reproductive parameter in a dose dependant manner. Similar harmful effects are obtained when these two metals are in mixture at 25 mg/L. Whereas more investigations are required, at the sight of these outcomes, we could assume there is no combination effect when cadmium and lead chlorides are in mixture. We also observed that cadmium delays the occurrence of different embryogenic stages. So it disturbed cell division. These observations are in accordance with previous studies analysing from a histological point of view the *Xenopus* oocyte maturation in cadmium contaminated media, where different kinds of atypical structures on the chromosomal formations (pronuclei, ectopic and disorganized spindles) have been reported. Cadmium also decreases fertilization whatever the male or the female gametes have been pre-exposed. But the fertilization success is more affected when oocytes are the Cd pre-exposed ones. Furthermore, no fertilization are able to reach the stage 2 in this condition. Our results highlight that cadmium altered *Xenopus* reproduction, affecting fertilization success and embryogenesis, preventing the formation of tadpoles. Analysing earlier stages will procured complementary information to the FETAX test. Moreover oocytes seem to be particularly threatened, and let suggest they could be considered as early and sensitive endpoint (and target) to assess environmental contaminants effects.

WE229
Effects of environmental stressors on the amphibian' pathogen Saprolegnia australis
S.A. Costa, Universidade de Aveiro / Department of Biology; C. Felix, Aveiro University / Depertement of Biology and CESAM; J. da Costa, T. Rocha-Santos, University of Aveiro / Department of Chemistry; A. Alves, CESAM University of Aveiro / Department of Biology; I. Lopes, University of Aveiro / Biology Department CESAM
Saprolegniasis is the common term used to report oomycete water mold infections. They have been responsible for large economic losses on aquaculture due eggs and fish larvae infection. As well, amphibian natural populations are also strongly affected by such pathogenic agents. Water mold infections have been documented and linked to amphibian population declines worldwide. These fungus-like organisms are in their majority saprobes, but are capable of parasitism and may act as opportunistic pathogens (e.g.cutaneous injuries). Besides, effects of water molds on amphibians appear to be influenced by several environmental factors, including temperature, pH and ultraviolet-B radiation. The present work aimed at understanding the effects that environmental changes may cause on amphibian pathogens. To achieve this objective, the pathogenic agent, *Saprolegnia australis*, was exposed to different levels of NaCl, seawater and acid mine drainage (AMD). Ecotoxicological assays were carried by exposing the mold, in PGA culture medium with different NaCl concentrations (ranging from 4.9 $mScm^{-1}$ to 54.9 $mScm^{-1}$), AMD dilutions (with dilutions ranging from 0% to 100%) and seawater (concentrations equivalent to NaCl solutions conductivity and the highest tested concentration being the one corresponding to SW). At the end of the assay, vegetative growth, biomass production, extracellular enzymatic activity and mycelium chemical composition were assessed in *S. australis* exposed under control and contaminated conditions. Results from mycelial growth of *S. australis* showed no effect on vegetative colony growth exposed to NaCl. However, a significant growth inhibition relatively to the control was observed when the mold was exposed to 0%, 25%, and 50% of AMD effluent dilution. For biomass production, results showed that NaCl and SW appears to have similar effect concentration values (EC_{20}= 47.0 $mScm^{-1}$ and EC_{20}= 41.7 $mScm^{-1}$ respectively). Regarding the quantity of biomass produced under effluent exposure, a reduction of 80% was observed at the AMD dilution of 75%. NaCl and AMD effluent also exerted effects on extracellular enzymatic activity. Under NaCl exposure, the water molt increase the gelatin and casein degradation and decrease lipase activity on the highest concentration. In general, effluent decreased the degradation of used substrates.

WE230
Biomarkers of oxidative stress in lizards from crops with different management intensity
M. Ortiz Santaliestra, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; M. Biaginni, University of Florence / Museo di Storia Naturale Sezione de Zoologia La Specola; S. Costa, E. Fasola, B. Santos, University of Aveiro / CESAM Departamento de Biologia; I. Lopes, University of Aveiro / Biology Department CESAM; C. Corti, University of Florence / Museo di Storia Naturale Sezione di Zoologia La Specola
Reptiles are an understudied group in ecotoxicology and little is known about the effects of pesticides on them. Several studies have shown the presence of some species within crop fields, with the consequent risk of becoming exposed to pesticides, and also that increasing intensity of agricultural management could compromise fitness in several lizard populations. The metabolism of pesticides in the organism produces reactive oxygen substances (ROS), which are normally neutralized by the antioxidant system. When the production of ROS surpasses the capacity of this system, the non-neutralized ROS may damage different structures of the cells, causing oxidative stress. We compared oxidative stress biomarkers among populations of two species of lizards (*Podarcis siculus* and *P. muralis*) inhabiting olive orchards and vineyard with a different degree of management (from organic fields to intensively managed crops) at Montepaldi Farm (Tuscany, Italy). We did not find any effect of species or gender on biomarkers, but the tail integrity influenced the outcome of glutathione concentrations and body condition. TBARS, an indicator of lipid peroxidation, increased concentration was associated with increased intensity of management in olive orchards. The enzymatic activity of glutathione peroxidase was reduced with respect to organic fields in olive orchards with an intermediate management intensity but not in those intensively managed, which could indicate a consumption of the enzyme at low pesticide concentrations that would eventually end up in new synthesis under increasing concentrations. However, responses of these two variables were only significant when considering lizards with regenerated tails, but not in animals with intact tails. A possible explanation for this result could be that of an energetic trade-off between the regenerative process and the antioxidant system, however further research is needed to unveil such kind of interaction. Our results highlight the importance of running integrated assessments of population health in order to understand the impacts of agricultural intensity in reptiles. The lack of basic ecotoxicological data and standard test methods for reptiles makes especially interesting this type of integrated field approaches for pesticide risk assessment in reptiles

Science based strategies for the environmental assessment and management of pharmaceuticals and veterinary medicines (P)

WE231
TOXICITY EVALUATION OF OZONE-TREATED WASTEWATER FROM A PHARMACEUTICAL MANUFACTURING FACILITY
J.G. Tell, Merck & Company, Inc. / Global Safety the Environment; R. Watts, K. de Bruin, Merck Sharp & Dohme; A. Vlaski, A. Haener, ARCADIS; J. Rijk, M. Migchielsen, WIL Research Europe BV
MSD is currently implementing a multi-year initiative to improve wastewater treatment and implement water sustainability projects at manufacturing sites worldwide. As part of the improvements, a pharmaceutical formulation site is installing two new wastewater treatment plants (WWTPs) for waste streams containing Active Pharmaceutical Ingredients (APIs) from two production areas before discharge to the municipal WWTP. Ozone was identified as a potential Best Available Technology (BAT) for treating a broad spectrum of APIs and was confirmed to be feasible for this application based on waste stream characteristics. Bench-top testing of ozone treatment was conducted using collected waste stream samples from the two production areas to verify removal of APIs below the required discharge concentrations established for no environmental impact. Based on the testing, an optimal ozone dose range and contact time were established (range of 50 mg O_3/L at 30 min contact/reaction time to 100 mg O_3/L at 15 min contact/reaction time). The potential negative impact of ozone treatment on water quality, specifically related to toxicity of the future treated effluent discharges, was addressed in a toxicity testing program. This included the following toxicity analyses for waste streams from the two different discharge points before and after

bench-top ozone treatment: Algae and *Daphnia* toxicity testing Estrogenic and Androgenic hormonal activity testing Bio-respirometry and 21 days DOC elimination testing. All toxicity, hormonal activity and biodegradability tests indicated the reduction of toxic effects in the tested waste streams after ozone treatment. These results are in conjunction with the observed API removal and confirm ozone as BAT for treatment of these API-containing waste streams.

WE232
EFFECTIVE REMOVAL OF ACTIVE PHARMACEUTICAL INGREDIENTS FROM INDUSTRIAL WASTEWATER
R. Watts, M. Collett, Merck Sharp & Dohme; P. Ross, M. DeMarco, ARCADIS; D. Vughs, KWR Watercycle Research Institute
MSD is currently implementing a multi-year initiative to improve wastewater treatment and implement water sustainability projects at manufacturing sites worldwide. As part of the improvements an initial literature screening on Best Available Technology (BAT) for the removal of Active Pharmaceutical Ingredients (APIs) was completed. Numerous articles describe possible techniques for the removal of APIs from wastewater, and ozone is generally reported as an efficient API removal/destruction technology. However, a range of ozone dosages up to 120 mg/L are reported depending on the wastewater matrix. In general, the rule of thumb for ozone (O_3) dosage would be a factor 3 or 4 to 1 per unit of chemical oxygen demand (COD). For industrial wastewaters with a high COD, this would result in very high ozone dosages which can translate into high investment and operating costs. During this study several industrial wastewater streams, with varied compositions including 20 different APIs, were sampled and bench scale tests with ozone were performed. A dosage range of 0.01 to 4.4 mg O_3/mg COD was applied during testing. For each API, a method was developed using Ultra Performance Liquid Chromatography – Mass Spectrometry (UPLC-MS/MS) to analyze the APIs in wastewater at concentrations as low as 0.1 μg/L. Results showed that good API removal efficiencies could be achieved for wastewater matrix COD levels as high as 5300 mg/L. Counter to the general perception, it was found that low dosages of 10 mg-O_3/L yielded as much as 70% removal for some APIs. Extreme ozone dosages of up to 3000 mg O_3/L resulted in 99.999% removal of specific APIs in highly concentrated waste streams. Ozone treatment provided the required removal efficiencies for 18 of the 20 APIs tested. Widespread application of effective API removal from wastewater remains a major challenge. However results from this work show that ozone treatment can be an effective solution for a range of APIs and wastewater matrices. The required dosages for API destruction were lower than initially expected, resulting in a cost effective solution.

WE233
Experience with AstraZeneca's Environmental Reference Concentration (ERC) Policy - Managing API Emissions for Internal and External Manufacturing Facilities.
B. Dillon, AstraZeneca / AstraZeneca Global Environment; K. Hutchinson; C. Hargreaves, Astrazeneca UK Ltd / AstraZeneca Global Environment
The issue of Pharmaceuticals in the Environment has received increasing attention in both academic literature and wider media of recent. Whilst Environmental Risk Assessments are required for patient use of new medicines as part of the regulatory submission to health authorities within the EU and USA, there remains a lack of guidance associated with potential impact from Active Pharmaceutical Ingredient (API) emissions from manufacturing. In this poster, we outline AstraZeneca's Environmental Reference Concentration (ERC) concept and its application to manufacturing sites both internally and externally as a tool for the risk management of API discharges to the aquatic environment. The Environmental Reference Concentration is defined as "the average concentration of an API in the receiving surface water environment that, based on current scientific knowledge, would be unlikely to result in any adverse long term effects". AstraZeneca have previously published our approach to monitoring emissions through the ERC procedure.[1] This poster aims to highlight our application and experience of the procedure *via* both practical and theoretical risk based assessments from both internal sites and external Contract Manufacturing Organisation (CMO) suppliers. WE234
Toxicity assessments of the selected sulphonamides solutions after ozonation in comparison to oxidation by fungal peroxygenase
N. Lemańska-Malinowska, Environmental Biotechnology Department; Z. Gajda-Meissner, T.F. Fernandes, Heriot-Watt University / School of Life Sciences
Veterinary drugs from the sulphonamides group (SAs), such as sulfamethazine (SMZ) and sulfadiazine (SDZ), are the oldest chemotherapeutic agents used for antimicrobial therapy and due to their bioactivity, they still play an important role. Very good results in the decomposition of these drugs in the aquatic environment were achieved by ozonation and using an oxidation process with unspecific peroxygenase from *Agrocybe aegerita* (*Aae*UPO). Nonetheless, special attention should be paid to the risk of by-products' formation, which may cause potential toxic effects on the living organisms. Therefore, the aim of this study was to compare the acute toxicity of SMZ and SDZ before and after both processes in a range of trophic levels. For this purpose, toxicity tests on *Vibrio fischeri*, *Pseudokirchneriella subcapitatum (CCAP 278/4)* and *Daphnia magna* were conducted, as described below. Toxicity tests on *Vibrio fischeri* bacteria were carried out using Microtox® analyser according to the Whole Effluent Toxicity (WET) test procedure. The effect of test solutions on the growth of the *Pseudokirchneriella subcapitatum (CCAP 278/4, green algae)* was measured as the rate of change of biomass. *Daphnia* acute toxicity tests were performed according to the OECD guideline 202 as range finding and definitive tests. The 24 h and 48 h EC_{50} values were calculated using SigmaPlot® software. The results obtained from toxicity tests were compared. No EC_{50} values could be calculated for the test with bacteria. SDZ and SMZ caused 50% of algae growth inhibition after 72 h of exposure at concentration 4.95% v/v and 6.54 % v/v respectively. EC_{50} values after 72 hours were 9.82% v/v and 9.83% v/v. For the freshwater crustacean the EC_{50} values were in the range 25.98- 33.55 %. It is concluded, that the ozonation process significantly decreased toxicity of the samples. For the enzymatic oxidation of selected SAs tests on *V. fischeri* showed a EC_{50} equal to 50.69 % for SDZ solution after this process was applied. SDZ and SMZ caused 50% of *P. subcapitatum* growth inhibition after 24 hours of exposure at concentration 5.14% v/v and 4.83 % v/v, respectively. After 72 h exposure the growth of algae was almost completely inhibited. EC_{50} values for *D. magna* test were in the range 14.54- 15.37 %. In general, SMZ and SDZ mixtures before and after ozonation are much less toxic when compared to the enzymatic oxidation process.

WE235
Difference of physiological activities of pharmaceuticals of wastewater between UK and Japan
H. ZHANG; M. Ihara, S. Hanamoto, N. Nakada, Kyoto University; M.D. Juergens, Centre for Ecology and Hydrology / Wallingford; A. Johnson, CEH Wallingford / Wallingford; H. Tanaka, Kyoto University
Pharmaceuticals have been widely detected in water environment at low concentrations. However, concern has been raised on their potential risks to human and aquatic species, because they are designed to be biologically active. To better understand this concern, we must know the physiological activity of pharmaceuticals in waters based on their modes of action (MoAs). One of the most important MoAs is interaction with G-protein coupled receptors (GPCRs). Untill now, we have detected physiological activities of GPCR-acting pharmaceuticals against some class of GPCRs in secondary effluent (SE) of wastewater treatment plants (WWTPs) in Japan by using *in vitro* transforming growth factor-α (TGFα) shedding assay. However, the situation in other countries is still unclear. In this study, we measured and compared the physiological activities of GPCR-acting pharmaceuticals in SE of WWTPs in UK and Japan by using *in vitro* TGFα shedding assay. We measured the antagonistic activities of pharmaceuticals against angiotensin (AT1), dopamine (D2), acetylcholine (M1), adrenergic (β1), and histamine (H1) receptors. Activities detected in waters were quantified as antagonist equivalent quantities (EQs). Concentrations of sulpiride (antagonist for D2 receptor) and metoprolol (antagonist for β1 receptor) were analyzed by LC-MS/MS in parallel. We compared the EQs, as measured by the TGFα shedding assay, with concentrations of corresponding pharmaceuticals, and investigated whether measured antagonistic activities in the wastewater could be explained by these known pharmaceuticals. In addition, in order to investigate more detail how different physiologocal activities of pharmaceuticals in SEs between UK and Japan, we fractionated SEs, and compared the EQs in each fraction between UK and Japan sample. If the fraction in which highest EQ is detected is different between UK and Japan samples, it means that corresponding pharmaceuticals for detected EQs are different between UK and Japan.

WE236
Case Studies Demonstrating the Advancement of Wastewater Management in the Pharmaceutical Industry
J.G. Tell, Merck & Company, Inc. / Global Safety the Environment; D.J. Caldwell, Johnson & Johnson
Across the human health pharmaceutical industry, we make a vast and diverse portfolio of products, each of which can have environmental risks. Good stewardship includes understanding the potential environmental and social implications and employing life-cycle thinking and tools to minimize any potential environmental risks – from the early stages of product design, to formulation and manufacturing, to the product's impacts during use and final disposal of residual product. EcoPharmacoStewardship is the framework that applies the widely-accepted principles of product stewardship. The three pillars of the framework are extended environmental risk assessment (eERA), extension of the scientific knowledge base (IMI-iPiE), and manufacturing effluent management, which is the focus of this poster. In 2011, a group of major pharmaceutical companies met to initiate a formal dialogue on the issue of best practices for managing pharmaceutical discharges from site operations. The companies shared their current programs at the time and embraced the concept of a maturity ladder that provides a mechanism for benchmarking across the industry (Caldwell, et al. 2015). Recently, these same companies reconvened to evaluate where each currently stands along the maturity ladder and to discuss changes and improvements to company-wide programs over time. This poster summarizes

some of the advances made by the pharmaceutical industry and the area for future work.

Perspective and challenges for generation of effects and fate data on innovative veterinary API
C. Durou, CEHTRA SARL; R. Magnier, A. Bauer, Ceva Santé Animale; B. Journel, CEHTRA SARL
An environmental impact assessment (EIA) has to be performed on the active pharmaceutical ingredient (API) for the market authorisation of veterinary medicines. The scientific guidelines are made publicly available by the EMA; among others, the guideline lists the minimum data requirements for the assessment of PBT/vPvB properties and how to conduct an EIA. The generation of fate and effect data is an iterative process. In a first Tier (A), the data requirements include the determination of physical-chemical properties (e.g. water solubility, n-octanol/water partition coefficient, fate properties (adsorption/desorption, route and rate of degradation) and short-term ecotoxicity dataset. In a second Tier (B), higher tier testing is required for fate (e.g. bioconcentration) and effects (long-term ecotoxicity) are requested. Finally, specific data may be requested on a case-by-case. For any new API, the available dataset on the active may be limited to the intended use of the VPI, pharmacological information and mode of action. While such data are important for the purposes of identifying emission route to environment and for designing an appropriate testing strategy, further information are necessary. Firstly, physico-chemical constitutes a key initial step given their importance as input data for exposure assessment and also as prerequisite for fate and effect data. As an example, behaviour and stability of new API in contact with water or standard aquatic test medium is missing at initiation of test program. Also, due to the mode of action but also in case of continuous emission to environment, long term toxicity studies may be preferred to short term studies. Next to these data gaps, the new API may exhibit one or more difficult to test properties for example, ionisation status is a common difficult to test property. Considering the overall, there is a need to order testing, allows flexibility in test program. The more relevant and reliable data are, the more robust is the environmental impact assessment. The purpose of this work is to initially review the data requirement for an EIA for a veterinary API which miss basic data need to define the suitable test method and test strategy.

WE238
Parasiticides - highly used veterinary pharmaceuticals and their impact on the environment
N. Adler, UBA FG IV 2.2 Arzneimittel; I. Ebert, Umweltbundesamt / Pharmaceuticals Department; J. Schoenfeld, Federal Environment Agency
Several groups of antiparasitic active substances are marketed and often used in food animals. While parasiticides are highly potent to eliminate endo- and ectoparasites, they have also effects on non-target organisms, such as dung flies and beetles and water flees. Environmental risk assessments that are submitted during the authorization process of veterinary pharmaceutical products show high risks for non-target organisms. In addition to these risks a parasiticide poses to the environment, some of these active substances are assessed to be hazardous. However, no products containing antiparasitic substances were refused to enter the market, so far. Instead, risk mitigation measures are defined to reduce the risks to an acceptable level. The poster presents risk assessments and the hazard characterization of different parasiticides and it will further discuss the defined risk mitigation measures regarding their suitability as well as the decisions made by regulators.

WE239
Methodology for considering the environmental risks of parasiticides in a risk-benefit assessment
J. Chapman, Environmental Department University of York; A. Boxall, University of York / Environment Department; C. Sinclair, The Food and Environment Research Agency / Centre for Chemical Safety and Stewardship; P. Howley, University of York; G. Jones, The Food and Environment Research Agency
As part of the authorization process, veterinary medicinal products (VMPs) require a benefit-risk assessment, which includes consideration of environmental risks. However, the environmental risks are not directly comparable to the therapeutic benefits (i.e., efficacy). In this study, we therefore developed an approach for communicating environmental risks of VMPs in a benefit-risk assessment. We investigated the risks 3 parasiticide compounds (ivermectin, moxidectin and fenbendazole) using summaries of product characteristics (SPCs), literature sources, and regulatory guidelines. To facilitate the benefit-risk comparison, a visual decision support matrix was developed and applied to each compound. We found the environmental risk matrix highlighted key tradeoffs and discrepancies in available data and could therefore be a valuable decision support tool. The improvement of methods to consider environmental risks in the benefit-risk assessment will aid decision-makers to select to best option and make the authorization process more transparent.

WE240
Towards an updated ERA for propranolol
D. Leverett, WCA-Environment Ltd; R.J. Brown, G. Merrington, wca consulting; A. Peters, wca; M. Gross, WCA Environment; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; S. Owen, AstraZeneca / Safety Health Environment; K. Hutchinson,
Propranolol is a non-selective adrenoreceptor blocker (β-blocker) and is prescribed to treat high blood pressure, cardiac arrhythmias, glaucoma, anxiety and migraines. As a result of its widespread use and pseudo-persistence propranolol is frequently detected in European sewage effluents and surface waters. Although an environmental risk assessment (ERA) undertaken according to European Medicine Agency (EMA) guidelines exists, and PNEC values for propranolol have previously been published (Murray-Smith et al. 2011), it is recommended that these are reviewed at regular intervals (Holm et al., 2012; Ågerstrand et al. 2015). A considerable quantity of new environmental effects and monitoring data for propranolol has been published in the scientific literature since the original assessment was conducted. We therefore present an updated ERA for propranolol, also conducted according to EMA guidelines, but taking account of all environmental fate and effects data published in the scientific literature to date. This will include an assesment of the measured environmental concentration (MEC) data for propranolol in both treated sewage treatment plant (STP) effluents and surface freshwaters. These will be compared with the predicted environmental concentrations (PECs) derived based on usage and dose data. Updated freshwater PNEC values for propranolol will also be presented, applying both deterministic and probabilistic derivation approaches. Finally, the MEC and PNEC data will be used to present updated Risk Characterisation Ratios (RCRs) for a series of different freshwater exposure scenarios for propranolol. Murray-Smith RJ, Coombe VT, Grönlund MH, Waern F, Baird JA. 2011. Managing emissions of active pharmaceutical ingredient from manufacturing facilities: An environmental quality standard approach. WE241
Review of ERA data submitted as part of pharmaceutical marketing authorisations
D. Leverett, WCA-Environment Ltd; R. Marks, M. Gross, WCA Environment; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; K. Hutchinson,
According to European Medicine Agency (EMA) guidelines, most marketing authorisation submissions for new pharmaceutical products require an Environmental Risk Assessment (ERA) of the active pharmaceutical ingredient (API) in the product, which should be submitted as part of the application. Exceptions to this requirement include so-called biologics (e.g. proteins, peptides, vitamins) where sufficient justification can be provided on a case-by-case basis that there is likely to be no significant environmental risk, and synthetic APIs where it can be shown that the new product will not lead to an increase in environmental exposure to the API. The ERA is conducted in two phases, with those substances meeting the criteria for further evaluation following a Phase I screening assessment proceeding to Phase II. In Phase II, a set of environmental fate and aquatic toxicity studies are required and a refined risk assessment for any compartments of concern may then need to be conducted in a Phase II, Tier B assessment. For products for which an EU-wide marketing authorisation is sought, the outcomes of each ERA are presented in a European Public Assessment Report (ePAR) which is publically available on the EMA website. However, the level and type of ERA information presented for each product can be extremely variable (especially for those applications submitted before 2006, when the current EMA guidelines were published). There may be no ePAR available at all, and ERA information contained in ePARs can vary from simple statements to a full presentation of hazard and exposure data. In addition, for generic APIs (i.e. those outside of patent) there are often a large number of applications (and therefore ePARs) for the same API. Nevertheless, a potentially large amount of environmental hazard data for APIs is available via these documents, and by cross-referencing the information on the EMA website for different products it may be possible to compile API hazard data, and potentially derive tentative PNEC values. In this poster we will present an analysis of the environment hazard information available on the EMA website for APIs in products for which an EU-wide marketing authorisation has been granted. In particular we will show data on the products for which a Phase II ERA was conducted, including (where possible) the environmental hazard data. We then present an evaluation of the hazard data for each API, and attempt to derive tentative PNECs using this data, according to EMA guidance.

WE242
Science-based Approaches to prioritise the Environmental Risks Posed by Legacy Human Medicinal Products

J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; S. Owen, AstraZeneca / Safety Health Environment; L. Gunnarsson, University of Exeter / Biosciences; A. Boxall, University of York / Environment Department

There are approximately 1500 Active Pharmaceutical Ingredients (APIs) in use today. However, the environmental risk of only a small proportion of these APIs has been assessed. Our ability to detect trace levels of pharmaceuticals in environmental matrices is also outpacing our capacity to assess these data within the context of environmental risk. Consequently, there is a real need for scientifically sound and pragmatic approaches to prioritize legacy APIs based on potential environmental risk for additional experimental testing or assessment under established regulatory guidelines. Over the past decade, several prioritization approaches have been proposed, primarily by the research community, for use on APIs and these have been used to identify substances for further scrutiny. These approaches vary in the methodologies used: some are exposure-based, some hazard-based and some take a risk-based approach; the majority of approaches have focused on aquatic exposures with only a few considering potential impacts in terrestrial and benthic environments; few have considered exposure of birds and mammals; and general approaches have been restricted to specific geographical regions and environmental compartments. As existing experimental data are only published for a small proportion of pharmaceuticals in use, most prioritization processes rely on existing data or information on read across from the human pharmacology and pre-clinical safety data and/or predictive models such as quantitative structure-activity relationships (QSARs). While our knowledge around human to environment read-across has increased over the past few years, there are still many uncertainties. The applicability of many of the predictive models that have been applied is questionable, particularly given that the majority of APIs are ionogenic in nature while most predictive models in use have been developed for neutral organic compounds. This presentation outlines a potential approach, that meets the criteria described above, that could be employed by the iPiE project. This approach pulls together some of the approaches that have been used previously but is much more holistic in terms of the compartments and risk-endpoints considered. It is our expectation that the approach could be parameterised and applied to different geographical regions to reflect differences in the API emission pathways to different compartments into the natural environment, levels of treatment, treatment connectivity and characteristics of the receiving environment.

WE243

QSAR Studies on the Potential Environmental Hazard of Pharmaceuticals

A. Sangion, P. Gramatica, University of Insubria / DiSTA

Active Pharmaceutical Ingredients (API) have become ubiquitary present in the environment, for this reason in 2006 the European Medicines Evaluation Agency (EMEA) published guidelines for the environmental risk assessment of human pharmaceuticals. Every environmental risk assessment (ERA) requires large amounts of data for each chemical but, unfortunately, information on PBT behaviour and ecotoxicological data are available only for a little percentage of API in literature and databases. We propose the characterization of the intrinsic hazard potential of pharmaceuticals by QSARs development and application. Some pharmaceuticals have been prioritized as potential PBTs by both Insubria PBT Index in QSARINS and US-EPA PBT Profiler in consensus approach. Then, from literature, we collected and carefully curated datasets for ecotoxicity data of species at different trophic levels (algae, Daphnia, fish) in order to consider a simplified aquatic ecosystem. For each species we developed ad hoc QSAR acute toxicity models, based on PaDEL molecular descriptors using OLS method and Genetic Algorithm for Variable Subset Selection in QSARINS software. All models are robust ($R^2 > 0.75$, $Q^2_{loo} > 0.70$) and externally validated (CCC> 0.85) on different splitting schemes. The structural Applicability Domain (AD) of the proposed models to pharmaceuticals without experimental data has been verified and demonstrated to be very high with the 74% of chemicals inside the AD for all the toxicity models. Moreover, reliable predictions from different models applied on a set of more than 1000 pharmaceuticals were combined by Principal Component Analysis (PCA) to find an ecotoxicity trend representative of the pharmaceuticals' toxicity in the whole aquatic ecosystem. This trend, called overall aquatic toxicity index (ATI), has been then modelled by molecular descriptors to obtain a QSAR model useful to highlight, directly from the chemical structure, the pharmaceuticals potentially most hazardous for the environment. This index and the predictions obtained by it could be used to refine procedures of input prevention and control at consumer level as well as *a priori* in the rational design of environmentally safer pharmaceuticals. Finally, we propose also interspecies correlation models to extrapolate information from one simpler trophic level (such as Daphnia) to another more complex (Fish), reducing the use of animal tests.

WE244

Effects of the beta-blocker metoprolol and the NSAID diclofenac on the embryonic development and health of brown trout Salmo trutta f. fario

H. Schmieg, Tübingen University / Animal Physiological Ecology; S. Schwarz, University of Tuebingen / Animal Physological Ecology; M. Scheurer, Water Technology Center TZW Karlsruhe; H.-. Köhler, University of Tuebingen / Institute of Evolution and Ecology Animal Physiological Ecology; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology

The discharge of human and veterinary pharmaceuticals into surface waters via wastewater treatment plants is a growing problem in Central Europe. However, despite the frequent detection of various substances in aquatic ecosystems, knowledge on their effects in biota is still scarce. Available data are based on standard biotests with model test organisms, which often lack ecological relevance. Two of the most frequently used pharmaceuticals and, hence, also frequently detected in surface waters, are the beta-blocker metoprolol and the NSAID (nonsteroidal anti-inflammatory drug) diclofenac. Our present study investigated the effects of metoprolol and diclofenac in brown trout, *Salmo trutta* f. *fario*, a species of high ecological relevance for Central Europe. The applied concentrations were 0.1, 1, 10, 100, and 1000 µg/L for metoprolol and 0.1, 0.5, 1, 10, 100 and 200 µg/L diclofenac, thus including several concentrations in ranges reported for German surface waters. Juvenile fish (six month post hatch) were exposed for 28 days. Investigated endpoints included biometric measurements, mortality, behavioural abnormalities, stress protein level (Hsp70) as a biomarker for proteotoxic stress and degree of lipid peroxides as a biomarker of oxidative stress. Furthermore, histology of liver, kidney, gill, and heart was assessed reflecting the overall health condition of trout. Additional tests with trout embryos and sac-fry stages were based on OECD guideline 212. Recorded endpoints in these tests were mortality, developmental parameters and histological condition. The diclofenac exposure of juveniles led to significantly increased mortality and to behavioural abnormalities already at low concentrations (0.1 µg/L). No such effect was seen for metoprolol. Furthermore, the stress protein level and the histology of liver and heart of trout remained unaltered. However, the erythrocyte to lymphocyte ratio in the heart of metoprolol-exposed brown trout was reduced compared to the control. Histological and biochemical investigation of the juvenile trout and fry will complement the study. Overall, our study aims at providing further information on the effects of environmentally relevant concentrations of frequently used pharmaceuticals in a species of high ecological relevance in Germany and adjacent countries.

WE245

Combined Environmental Risk Assessment for the Antiviral Pharmaceuticals Ganciclovir and Valganciclovir

J. Straub, F.Hoffmann-La Roche Ltd / Roche Group Safety Health Environmental Protection

An environmental risk assessment (ERA) was conducted for the antiviral, primarily anti-cytomegalovirus active pharmaceutical substances ganciclovir (GCV) and valganciclovir (VGCV). VGCV is the L-valine ester of GCV and a prodrug for the latter, formulated for better oral bioavailability; hence, the ERA focusses on GCV. Predicted environmental concentrations (PECs) for GCV were calculated for the relevant environmental compartments sewage treatment, surface waters and sediment, based on documented use data for both GCV and VGCV for Europe. Predicted no-effect concentrations (PNECs) for the same compartments were derived from chronic ecotoxicity tests. The ERA compares PEC with PNEC per compartment in the form of a risk characterisation ratio. Moreover, based on mutagenic and reprotoxic effects in mammals GCV is a CMR (carcinogenic, mutagenic, reprotoxic) substance; hence the fish early life stage test was extended to encompass reprotoxic endpoints. A PBT (persistence, bioaccumulation and high ecotoxicity) assessment complements the PEC/PNEC-based ERA.

WE246

Paradigm shift towards a substance-based environmental risk assessment of pharmaceuticals

I. Rönnefahrt, Federal Environment Agency / Section IV Environmental Risk Assessment of Pharmaceuticals; N. Adler, UBA FG IV 2.2 Arzneimittel

Even more than 10 years after implementing the environmental risk assessment (ERA) into the EU pharmaceutical legislation there is still a lack of data on fate and effects of active pharmaceutical substances. The reason for that is quite simple: A review program of 'legacy' products, which were approved before the ERA requirement was set, was never envisaged. But even for newly approved pharmaceuticals sometimes no full data sets essential for an ERA are available due to various reasons. In the pre-market phase an ERA is required for all new applications. This often leads to duplication of data and of assessments and hence, to a waste of resources. This may also lead to contradictory assessments and even to different risk mitigation measures for medicinal products intended for the same indication. The described problems with the functioning of the pharmaceutical legislation could largely be solved with a paradigm shift toward a substance-based ERA. One of the options which is currently discussed on an EU level is the establishment of a monograph system on active pharmaceutical substances. The aim of such a monograph system is to collate existing fate and effects data on active substances, to generate missing studies and data of high quality, to evaluate studies and to agree on the endpoints to be used for ERAs of medicinal products. Once established all authorizations of medicinal products would use the agreed endpoints from the monograph of the respective active substance to perform the ERA of the product. Overall, only a pre-market monograph systemon fate and effects data of active pharmaceutical substances in conjunction with an effective monitoring within the post-market surveillance and regular adjustments of these information to the scientific and technical progress will be able to ensure the environmental safety of medicinal products in use. This will ensure up-to-date risk assessments which are the vital base for any kind of risk management. Therefore a paradigm shift towards a substance based ERA and the collection of environmental information in substance files (monographs) will be the key measure to ensure the environmental safety of medicinal products in use. Challenges for the establishment of a monograph system are first of all clear rules on set up and management of consortia, rules on data protection, cost sharing etc. Examples of successful collaborations already exist in other legislative areas like REACH and biocides.

WE247

Mining Environmental Agency Databases: A Powerful Tool for Understanding the Fate of Pharmaceuticals and Personal Care Products

B. Hawdon, University of Portsmouth / Institute Marine Sciences; G.J. Watson, University of Portsmouth / Institute of Marine Sciences

As pharmaceutical use continues to increase so does the release of these potentially damaging compounds into the environment through treated and untreated sewage. This problem has been recognized since the early 90's but only now are policies being developed to deal with the problem. Many scientists and policy makers require more information on the long term release and fate of pharmaceuticals and personal care products. The Environmental Agency has been testing environmental samples with GCMS for a variety of pollutants since 1988 and every year more pollutants are added. Because of the Freedom of Information Act 2000 the Environmental Agency now will supply the data to the public upon request. To help direct our research we decided to test the usefulness of these databases. We requested data for variety of compounds including anti-inflammatories, anti-depressants, anti-convulsants, antibiotics, anti-cholesterol and hormone drugs for 2010- September 2015. We focussed on the Southern, Thames and Anglia region because of the diversity of populations and industries in those regions. The data we received was in Access format and contained a huge amount of information that needed some deciphering to understand what it offered. The data indicated constant collection of samples from hundreds of sites and the concentrations ranged from .001 μg to over 2000 μgs. Some of the pharmaceuticals with higher concentrations could be followed from sewage release through rivers to estuaries and coastal sites. Thus giving a better understanding of the movement and fate of these compounds. Some of the trends revealed from this data included monthly variation, annual variation, increase/decrease or constant concentrations, and geographical areas with higher levels of pharmaceuticals. At most sites the concentrations remained fairly constant, indicating flushing of pollutants, adherence to sediments or break down, but with continual releases. The mining of the databases built by the Environmental Agency through their monitoring programs is an important tool for following the fate of pharmaceuticals prescribed in the UK. This tool can be used in scientific and management collaborations to develop better policies and methods for dealing with this growing problem.

WE248

Integrated food security: mapping and selecting different indicators and metrics from sustainability till safety, veterinarian pharmaceutical case study

E. Boriani, Instituto di Ricerche Farmacologische Mario Negri; T. Hald, DTU FOOD GDSI

In food security, integration of data and knowledge across disciplines is needed to prevent food-related diseases, improve sustainability, traceability, quality, animal welfare, diminish food waste, have a clear picture of the environmental impact, improve communication to different stakeholders and introduce nutritional factors considering the enlarging need to "feed the planet". In this study, we propose a map of indicators and metrics along the production and consumption chain from "farm to fork ", in specific for an Italian pork product (Prosciutto cotto-ham), useful for decision making processes. Databases and predictive models are combined in a broad manner to find interconnections, important variables, and potential nodes to assess the overall sustainable nutrition security and improve elements such as traceability, detection of foodborne hazards, emissions in the environment, nutritious value and communication in every step of the value chain. Sustainability indicators and metrics from Life Cycle Assessment and Risk Assessment are integrated to provide a more holistic assessment of the food chain with particular attention to veterinarian pharmaceuticals case study. Certified products can gain increased credibility from the consumer, if adequate information is provided through all steps in the production chain from primary production to retail. The map considers human health risks (e.g. chemicals residues in the food, infectious agents, contaminants), benefits (e.g. nutritional values), environmental impacts (e.g. pharmaceuticals in the environment, energy consumption), and social impacts (e.g. in vulnerable population). The map helps to compare products or product chains, to identify critical steps, and to observe the problems, risks or benefit from several different perspectives. Advancements in life cycle impact assessment method development (P)

WE249

Bridging land transformation and occupation impacts with water use in life cycle assessment: linking green water consumption with ecosystem quality impacts in Amazonia

M.J. Lathuilliere, University of British Columbia / IRES; C. Bulle, CIRAIG - ESG - UQAM / Strategy corporate social responsibility; M.S. Johnson, University of British Columbia / Institute for Resources Environment and Sustainability Department of Earth Ocean and Atmospheric Sciences

The framework for assessing potential impacts of land transformation and occupation (LTO) has provided valuable guidance for quantifying mid-point impacts such as changes in erosion resistance or groundwater recharge. At the same time, the inclusion of water use in life cycle assessment (LCA) has filled important modeling gaps by considering potential effects of changes in water quality and quantity on human health and ecosystem quality. We propose to bridge land use with green water consumption (as soil moisture regenerated by precipitation) in a cause-effect chain reflecting changes to the atmospheric water balance through LTO. LTO affects the amount of green water consumed by the land through evapotranspiration, which can reduce precipitation downwind (mid-point impact), thereby affecting terrestrial ecosystems which are reliant on soil moisture (end-point impact). The mid-point impact modeling step derives the amount of reduced precipitation present in a river basin based on an internal evaporation recycling ratio. The end-point impact relies on differences in climate potential species richness resulting from reduced precipitation as a step to infer ecosystem damage. We apply the proposed method to Southern Amazonia which has experienced extensive deforestation for pasture and crops and whose agricultural frontier plays an important role in changing the atmospheric water balance of Amazonia. This new framework brings closer together the effects of LTO and water consumption which are often considered separately in LCA, but whose connection is particularly important in arid and semi-arid regions as well as highly seasonal areas where evapotranspiration and precipitation are closely coupled.

WE250

Combined environmental and economical inventory for a LCA and LCCA of an insurance

I. Bosch-Frigola, F. Coca, Universidad San Jorge; J. Val, D. Chinarro, San Jorge University; M. Pino, San Jorge University / Facultad ciencias de la salud

Increasingly, the environmental characteristics of a product are analyzed not only from environmentally point of view but also economical. Therefore, combined LCA (Life Cycle Assessment) and LCCA (Life Cycle Costs Assessment) methodologies have been progressively implemented and regularly applied to industrial activities or products but less put into practice on services activities or products. This study aims to develop a combined methodology between LCI (Life Cycle Inventory) and economical inventory costs applied to the insurance policy in order to perform a LCA-LCCA coupling study. One health insurance policy from an insurance company specialized in health and prevention (DKV Seguros a member of Munich Health) was considered as functional unit. The study includes the activity of the company headquarters located in Zaragoza and 61 offices throughout Spain during 2014. The system boundaries of the study are "cradle to grave" thus incorporating not only the phase of creating insurance (business coaching, marketing and vending), but also the phase of use by insured client. Disposal stage is also contemplated. Furthermore, the inventory includes in detail all transport associated with the activity: the receipt of raw materials, transport of waste to the treatment center, transport marketing activities and the displacement of the insured client to the appropriate medical center. These environmental data have been assembled to economic data, primarily costs associated with identified flows input/outpout. The costs allocation has been carried out through an ABC system (Activity Based Costing). Data obtained from the combined inventory has allowed to connect the economic information to the environmental information at every stage and provide a basis for diagnosing the environmental impact of an insurance throughout its life cycle, as well as the costs associated with these impacts. This data analysis provided useful results to establish new strategies of prevention in the insurance sector. *This work has been possible thanks to the financial support and the systematic data provided by the company DKV*

WE251

Freshwater Ecotoxicity as an environmental impact category to guide the selection of chemical-based products

M. Claessens, Chemours; C. Cooper, International Zinc Association / Department of Marine Sciences; M. Galay Burgos, ECETOC / Environmental Sciences; R. Hoke, E.I. DuPont de Nemours and Company / Haskell Global Centers for Health and Environmental Sciences; B. Hundt, D. Kolsch, Bayer Technology Services GmbH / on behalf of Covestro; J. Lharidon, LOREAL / Life Sciences Direction; N. Otte, Henkel AG Co KGaA; F. Palais, SOLVAY; F. Schmidt, BASF Schweiz AG / Institut for Environmental Research; D. Schowanek, Procter & Gamble / Brussels Innovation Center; T. Wolf, LOreal Research / Worldwide Regulatory

Affairs for Chemistry
There is increasing interest from regulators to apply life cycle based impact assessment methodologies to assess the environmental performance of chemicals and products and to include freshwater ecotoxicity as an impact category. Examples include initiatives on green chemistry in the US as well as the Grenelle Regulation in France and the EU's Single Market for Green Products Initiative that covers both fast moving consumer goods as well as durable goods (e.g. the Product Environmental Footprint, PEF, pilot projects). A key focus area of such initiatives is the assessment of the environmental impact of chemicals and specifically the application of the USEtox method for measuring freshwater ecotoxicological impacts. The extension of the traditional LCA methodology to include the ecotoxicological impacts of chemicals raises some fundamental issues both methodologically and conceptually with the accepted norm of using risk assessment approach to manage chemicals and ecolabel consumer goods, within industry and by regulators. At the same time, the scientific committees of the EU have outlined that the current prospective environmental risk assessment methodology is far from being realistic, i.e. not delivering an accurate approximation of the environmental impact of chemicals. However, there has been no detailed assessment of whether decisions based on a CDV (Critical Dilution Volume, EU Ecolabel key criterion) or USETox comparative ranking lead to real and meaningful differences in environmental impact. With this in mind, an ECETOC Task Force was assembled to conduct a scientific evaluation of USEtox and similar tools (e.g. CDV) with the goal of establishing their relevance to the real world and to provide guidance on how to interpret their results regarding selection/ranking of chemical based products. In addition, for the USEtox methodology in particular, the influence of LCA best practices on the results of the ecotoxicological impact assessment is studied, giving attention to data availability and quality as well as treatment of missing data. Finally, a comparison of the purpose and scope of LCA and risk assessment (RA) is performed in which the potential use of specific methods from RA within LCA is explored. Guidance will be offered on how both kinds of assessment can be used in conjunction or can complement each other. This poster presents the preliminary results of this task force's activities.

WE252
Lessons from the endogenous integration of life-cycle indicators into national energy models
D. García-Gusano, D. Iribarren, M. Martín-Gamboa, Instituto IMDEA Energía / Systems Analysis Unit; A. Lind, K. Espegren, Institute for Energy Technology (IFE); J. Dufour, Instituto IMDEA Energía / Systems Analysis Unit
Governments and decision-makers are increasingly aware of the need for assessing sustainability, which is particularly relevant to the energy sector. In this respect, life-cycle approaches are often use for the evaluation of energy systems. A key challenge is the implementation of the time dimension when using these approaches for the analysis of dynamic systems. The energy sector (both as a whole and at a lower scale) is a dynamic system. In fact, energy policies aim to guide the evolution of this system by defining performance targets e.g. in terms of greenhouse gas emissions. Energy systems modelling supports this type of policy-making process thanks to its suitability to deal with future scenarios and therefore with the time dimension. However, current modelling practices leave out a strong implementation of sustainability indicators in energy models. Within this context, the hybridisation of life-cycle and energy modelling approaches attempts to foster the strengths of both approaches while significantly overcoming their limitations. This work summarises the lessons learnt from the integration of life-cycle indicators into national energy models within the SuReTool project of the EEA/NILS Science and Sustainability programme (006/ABEL-CM-2014). The evolution of power generation in the business-as-usual scenario for Norway and Spain was analysed with a time frame from 2010 to 2050. Furthermore, the damage assessment of the involved technologies was carried out using the IMPACT 2002+ method. A number of life-cycle indicators (e.g., climate change, ecosystem quality and human health) were then endogenously integrated into the energy models of Norway and Spain. This soft-linking exercise enabled the analysis of the evolution of these life-cycle indicators, thus significantly enriching the interpretation of future energy scenarios. Emphasis is laid on the efforts made to mitigate concerns about double counting of emissions and imbalances in electricity trade processes. Overall, the interaction between life-cycle and energy systems modelling approaches is concluded to be advantageous. Nevertheless, further efforts are still required when it comes to strengthening the linkage between both approaches within a harmonised framework.

WE253
LAND USE LIFE CYCLE IMPACT ASSESSMENT: BRAZILIAN ECOSYSTEM SERVICES REGIONALIZATION
A. Raymundo Pavan, University of São Paulo; A. Ometto, University of São Paulo USP / Department of Production Engineering
There is a growing recognition that it is crucial to consider land use in the environmental assessment of products, especially those with a majority of their life cycle in biological processes (such as agriculture and forestry). This is an important issue for Brazil, which faces the challenge to overcome the dichotomy between production and environmental protection within the general framework of sustainable development. The present work aims to develop characterization factors (CFs) consistent with Life Cycle Assessment that estimate the impact of land use on ecosystem services for Brazil. The methodology involves four steps: i) creation of a spatial model; ii) expert consultation; iii) data collection and iv) CFs calculation. A literature review and characterization models analysis led to the choice of Brandão; Milà i Canals (2013) framework for Biotic Production Potential impact assessment as the reference to further refinement and adaptation. This work assumes that political boundaries don't reflect the dynamic nature of ecosystems, especially for countries with a large territorial area such as Brazil. Therefore, a set of criteria regarding the scientific relevance, representativity and data availability was used in order to define an appropriated biogeographical differentiation for Brazil. The results showed that the ecoregions spatial scale is a suitable choice since it synthesizes ecological, geological, botanical, climatological and hydrological patterns. Moreover, based on the criteria presented in Koellner et al. (2013) the land use classification conducted by the Brazilian Institute of Geography and Statistics was adapted for CFs calculation. In conclusion, it was possible to obtain a regionalized model for land use impact assessment with increased robustness. The next steps include consulting experts in order to identify contributions on relevance of the model assumptions and parameters, followed by the data collection and CFs calculation. Principles for life cycle inventories of land use on a global scale. **International Journal of Life Cycle Assessment,** v. 18, n. 6, p. 1203-1215, 2013.

WE254
Linking water pollution to impacts on water resources
C. Pradinaud, IRSTEA Montpellier / UMR ITAP ELSA; M. Núñez, National Research Institute of Science and Technology for Environment and Agriculture Irstea; P. Roux, National Research Institute of Science and Technology for Environment and Agriculture Irstea / UMR ITAP ELSA; G. Junqua, Ecole des Mines dAlès / LGEI; R.K. Rosenbaum, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR ITAP
Life Cycle Assessment (LCA) of water consumption considers impacts on the Area of Protection (AoP) "Resources", depending on the regeneration time. However, there is no method that links water pollution to the AoP resources. Because of the increasing concern over the state of water resources available for future generation, this study aims to answer if there is a link between water pollution and impacts on water resources. This talk proposes a definition of freshwater resource as part of the AoP resources and why it will be relevant to consider impacts on that AoP for certain types of pollution. A key element to clarify this debate is the concept of water functionality. The pollution in present time has potential impacts on human health and ecosystems, but beyond a certain time period persistent substances may rather contribute to potential impacts on water resources (i.e. their functionality) as it becomes increasingly uncertain to predict how the resource will be used in the future. Thus, the functionality loss due to pollution may be considered as damage to the water resource. In order to consider that link in LCIA we propose a new water use impact pathway which can be integrated into existing impact categories. Results proposed take into account the fact that it is crucial not to double-count the impacts which are already assessed on human health and ecosystem quality. For that purpose, and to fit well with the definition given to the water resource, two phenomena are considered: the persistence of pollutants in a water body and the pollution of a water resource currently unused.

WE255
Towards a new midpoint indicator for including noise impacts from mobility in life cycle assessment.
R. Meyer, LIST / Environmental Research and Innovation; E. Benetto, Luxembourg Institute of Science and Technology (LIST) / Environmental Research and Innovation; C. Lavandier, Université de Cergy-Pontoise / MRTe
Recent studies have shown that noise emissions from mobility have a significant impact on the exposed population's health. The inclusion of noise in Life Cycle Assessment (LCA) has become a necessity as noise may represent the major contributor to Human Health when the LCA study focuses on vehicles or when transports are a major part of the foreground system. Despite its importance, only a few methodological attempts to include the impacts of noise emissions in LCA have been made and a consensual approach is not available yet. According to the relevant epidemiologic literature, the work presented here considers the level of noise at which a given population is exposed as indicator. Noise emission and propagation simulation software is used to derive the exposition of a given population to noise, for the specific GIS model of the city of Lyon (France), considered as a proxy of emission, propagation and exposure conditions. The exposure of population is calculated in different geographic situations and periods of the day. The changes of exposure are then studied to understand the impact of an increment of vehicle.kilometers (vkm). A set of characterization factors (CFs), dependent of geographic characteristics and period of the day, is derived. The CFs

allow linking the inventory in vkm to a change in the population exposure. Later on, the change will then be linked to an impact on Human Health (expressed in DALYs), allowing a systematic integration of noise impact in standard LCA.

WE256

Pollinators in LCA: relevance and challenges

E. Crenna, University of Milano Bicocca; S. Sala, European Commission - Joint Research Centre / Sustainability Assessment unit

Human activities are threatening biodiversity at an unprecedented scale and pace, thus potentially affecting also the provision of critical ecosystem services, including insect pollination. Insect pollinators play an essential functional role in terrestrial ecosystems, supporting ecological stability and food security worldwide. Therefore, assessing impact on pollinators is fundamental in any effort aiming at enhancing the environmental sustainability of human production and consumption, especially in the agri-food supply chains. Different drivers are leading to pollinator populations' declines. Improving a supply-chain oriented assessment of the occurrence of pressure and impacts on pollinators is needed. However, current methodologies assessing impact along supply chains, such as life cycle assessment (LCA), miss to assess impact on pollinators. In fact, none of the existing life cycle impact assessment (LCIA) models effectively accounts for pollinators. Some LCIA models have mentioned pollination, but none has presented key drivers of impact and a proposal for integrating pollinators as target group for biodiversity protection within an LCIA framework. In order to devise a pathway towards the inclusion of impact on pollinators in LCIA, we conducted a literature review of environmental and anthropogenic pressures acting on insect pollinators, potentially threatening pollination services. Based on the evidence in literature, we identified and described eight potential impact drivers, primarily deriving from industrial development and intensive agricultural practice: 1) intensified land use as a result of uncontrolled expansion of urban areas and modern agricultural practices; 2) use of pesticides; 3) presence of invasive alien plants; 4) competition with invasive alien pollinator species; 5) global and local climate change; 6) spread of pests and pathogens; 7) electro-magnetic pollution and 8) genetically modified crops. To account for these drivers in LCIA, there are specific modeling needs. Hence, the current study provide recommendation on how future research should be oriented to improve the current models and how novel indicators should be developed in order to cover the existing conceptual and methodological gaps.

WE257

Effect factors for terrestrial acidification in Brazil

N.C. Mendes, Technical University of Denmark; A. Laurent, Technical University of Denmark / DTU Management Engineering Division for Quantitative Sustainability Assessment; M. Hauschild, DTU Management Engineering / DTU Management Engineering

To support the increased use of existing Life Cycle Impact Assessment (LCIA) methodologies across the world, new methodological elements have been developed towards spatially resolved impact assessment. Spatially resolved methods could better capture the differences of regional environmental conditions, which is an essential approach considering countries like Brazil, with high biodiversity. Previous studies have assessed the impacts of terrestrial acidification from the estimations of the potential losses of vascular plants species richness as a result of exposure to acidifying substances for 13 biomes, with 2409 species addressed for whole world. In this context this work aims to provide spatially-differentiated effect factors (EF) for terrestrial acidification in Brazil and support the development of spatially-differentiated characterization factors for Brazil. In order to maintain compatibility with existing LCIA methods the effect factors were developed using the framework adopted by LC-Impact and Impact World+ methods. Soil pH was used as an indicator of soil acidity to predict plant occurrences. From the number of plant species occuring at each 0.1 pH unit response relationships of species richness and soil pH were developed. The species richness in each ecoregion were transformed into an empirical potentially not occurring fraction, which is a zero-to-one measure used to represent the presence or absence of species. The set of data consists of 976345 records of plants occurrences in Brazil, represented by 33167 species, indicating that this is a comprehensive study. Maps of soil pH in Brazil were extracted at 1-km resolution and pH values were extracted for the depth range of 0-30cm. For each ecoregion, species richness was plotted against soil pH and the exposure-response curves for acidification described the behavior of plant species in a certain region when it is exposed to acidic conditions. From these curves it was possible to derive the effect factors for terrestrial acidification. The results of this work show that spatial differentiation is meaningful when it is possible to combine fine spatial resolutions and highly representative data and this approach can be applied for other impact categories and regions, and contribute to the development of spatial differentiated LCIA methodologies.

WE258

A regionalised characterisation factor for freshwater and marine eutrophication applied at the territorial scale: method and application in an agricultural French catchment.

L. Nitschelm, J. Aubin, INRA , Agrocampus Ouest / UMR SAS; C. Dupont, C. Gascuel, INRA Institut National de la Recherche Agronomique / UMR SAS; C. Walter, INRA Institut National de la Recherche Agronomique

Agriculture has impacts on the environment that range from local (eutrophication) and regional (acidification) to global (climate change) scales. To help local stakeholders manage agricultural activities, environmental impacts should be assessed at the territorial level by taking into account its biophysical characteristics. In this context, the Spatialised Territorial Life Cycle Assessment (STLCA) method was developed (Nitschelm et al. 2015). In this method, environmental impacts from agricultural territories are defined by integrating the location of emission and fate of pollutants and characterising the biophysical context. In this study, we focus on agricultural territories, which we define as territories in which most land uses or economic activities are based on agriculture. We focus here on eutrophication, because it is a major impact of agriculture at the local scale and could therefore benefit from spatial differentiation. The objectives of this study are (1) to develop two characterisation factors for freshwater and marine eutrophication, each of which considers a spatially differentiated fate for each compound responsible for eutrophication as well as a sensitivity factor of the surrounding environment to eutrophication, and (2) to apply these new characterisation factors to a case study of the "Lieue de Grève" catchment, located in northern Brittany, France. The approach developed is based on including site-specific fate factors and sensitivity at the catchment scale. For freshwater, phosphorus is considered as the limiting element for eutrophication. For marine water, we consider that nitrogen is the limiting element. Both fate factors are predicted using the Nutting-P and Nutting-N models (Dupas et al. 2015), which predict the distribution of nutrients emitted from farms into soil and water systems. Both coastal and river sensitivity indices were calculated using morphological and hydrological characteristics of river-basin and coastal areas. The method was then applied to the Lieue de Grève, which experiences eutrophication problems, and compared to a standard LCA. When using STLCA, predicted eutrophication impact was 54% lower than that using CML-IA CFs, due to differences in environmental sensitivity. Importantly, impact hotspots in the territory were identified. This study shows the relevance of using spatially explicit data when estimating local impacts in LCA.

WE259

Spatial variation of secondary inorganic PM2.5 exposure and human health impact: a case study on milk production

O. Jolliet, University of Michigan; K. Stylianou, University of Michigan - School of Public Health / Environmental Health Sciences; C. Tessum, J. Marshall, University of Minnesota / Civil Environmental and Geo Engineering; J. Hill, University of Minnesota / Bioproducts and Biosystems Engineering

Purpose: Secondary $PM_{2.5}$ human health impacts in life cycle assessment (LCA) are currently based on linear and simplified assumptions that may lead to a potential double counting. The aim of this study is to provide spatial intake fractions (iF) for secondary inorganic $PM_{2.5}$ for the U.S. and apply them to a case study that investigates environmental and nutritional effects associated with increased milk consumption. *Methods:* Unitary emissions of NH_3, NO_x, SO_2, and $PM_{2.5}$ are modelled in the Intervention Model for Air Pollution (InMAP) in three U.S. locations: Wisconsin (WI), New Jersey (NJ), and New York (NY. iFs by precursor are characterized for each emission location and are then applied to a case study investigating the environmental and nutritional health effects linked to adding one milk serving produced in WI, NJ, and NY. Environmental health impacts from global warming and particulate matter are compared to nutritional effects associated with milk consumption such as colorectal cancer, stroke, and prostate cancer using the Combined Nutritional and Environmental Life Cycle Assessment (CONE-LCA) framework. *Results and Discussion*: Intake fractions ranking is consistent between locations with $PM_{2.5}$ having the highest iFs, followed by NH_3, SO_2, and NO_x. There is a considerable spatial variation of exposure per precursor between locations due to main factors of influence. NJ shows the highest iFs followed by WI and NY. For example, the NJ estimate for NH_3 is about an order of magnitude higher than that in WI and about 15 times higher than that in NY, reflecting the higher population density. The relative ratios for NH_3/SO_2 iFs varies between locations: the ratio ranges from 18in New Jersey (abundant NO_x and SO_2 but limited NH_3) to 1.7 in Wisconsin (abundant NH_3 but limited NO_x and SO_2). Finally, adding one serving of milk to the average U.S. diet leads to an overall health benefit due to nutritional benefits if production was to occur in NY or WI while this benefit is considerably reduced when milk is produced in NJ due to substantial PM-related health effects. Conclusion: Preliminary results support a spatial variation of secondary $PM_{2.5}$ exposure in the U.S. and suggest an overestimation of health effects in regions with high NH_3 emissions or underestimation in regions limited in NH_3 from current estimates. PM and dairy related exposures and impacts are substantially greater if emissions occur in in highly populated regions limited by NH_3.

Prospects by WULCA in the impact modelling of water consumption in LCA

M. Núñez, National Research Institute of Science and Technology for Environment and Agriculture Irstea; P. Roux, National Research Institute of Science and Technology for Environment and Agriculture Irstea / UMR ITAP ELSA; J.C. Bare, US EPA / National Risk Management Research Laboratory; C.

Bouchard, Universite Laval; A. Boulay, CIRAIG - École Polytechnique de Montréal / Chemical engineering department; C. Bulle, UQAM, Ecole des sciences de la gestion; M.J. Lathuilliere, University of British Columbia / IRES; M. Margni, CIRAIG - École Polytechnique de Montréal / Mathematical and Industrial engineering; S. Pfister, ETH Zurich / Institute of Environmental Engineering; F. Verones, NTNU / Department of Energy and Process Engineering; R.K. Rosenbaum, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR ITAP
Much progress has been made in the characterisation of impacts of water use and consumption in the last few years in LCA. Today, there are many generic midpoint scarcity/stress indexes (not human-, ecosystem- and resources- oriented) as well as specific endpoint-oriented methods that cover complementary cause-effect chains. Scarcity indexes are easier to use and have generally seen more application than endpoint methods, even though they rather represent competition to access water than potential impacts. On the one hand, scarcity indexes are good for water footprinting but their environmental relevance, especially for ecosystems, is limited. On the other hand, endpoint methods are ecologically relevant but they are incompatible with themselves in their current form, which prevents their integration in a single indicator. To further develop water consumption indicators in LCA, the UNEP/SETAC Life Cycle Initiative Water Use in LCA (WULCA) Working Group is currently working on the development of a framework focusing on the ecosystem quality area of protection. It adopts the generic mechanistic structure of characterisation factors used to assess emissions, with a fate factor (FF), an exposure factor and an effect factor. The FF is based on water mass balances that reproduce the hydrological cycle and the interconnections between compartments which are the base of the water cycle. It is a multimedia multipathway model that shows how the extraction of water from a compartment influences water availability in other compartments. The connection between the different water compartments helps in solving important methodological issues, such as the integration of soil moisture (i.e., green water) in the assessment of water use impacts, and the potential double counting of land use impacts on the water cycle in the land use and the water use impact categories. The exposure factor estimates the capacity of biodiversity to adapt to reduced water in a given water compartment by accessing alternative water sources. The effect factor accounts for the effects on taxa that are not able to counterbalance the lack of water. Further sub-factors, such as a severity factor, might be added to this framework. This framework clearly expands the way modelling water consumption has been considered in LCA.

Biodegradability assessments of organic substances and polymers (P)

Workshop on the current status and steps needed to improve the OECD 306 marine biodegradation screening test
G. Whale, Shell Health / Shell Health; T. Martin, R. Davenport, Newcastle University; M. Galay-Burgos, ECETOC; B. Rowles, Cefas / OCNS; A. Ott, Newcastle University; J. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment
Recent ECETOC workshops have recommended a series of modifications and enhancements to existing OECD biodegradation screening tests to deliver more robust methods for assessing persistence. Specific enhancements investigated included enhanced test durations and investigating the impact of biomass density and diversity on the probability of observing biodegradability. These proposed steps were designed to minimise the high variability and poor reliability previously reported in OECD biodegradation screening tests, such as the OECD 306 marine biodegradation test, whilst increasing the ecological relevance of such studies. The Cefic-LRi funded Eco11 investigated and validated these enhancements, producing a framework for selecting the most suitable inocula cell concentration method for activated sludge (c.f. OECD 301) and marine tests (c.f. OECD 306). As a follow up during February 2015 the UK Centre for Environment, Fisheries and Aquaculture Science (Cefas) hosted an international workshop on the OECD 306 test in Lowestoft which was convened to: Initiate discussions regarding the current applications and use of the OECD 306 test; Discuss current limitations and sources of variability of the test; Provide an overview of the relevant findings and recommendations of the Eco 11 project; Discuss potential improvements and provide hands-on lab-based training of procedures used to concentrate inocula from seawater; Make recommendations for selection of test chemical and scope of a future ring test. The workshop agreed that there was too much variability in existing marine biodegradation screening tests and that there was a need, which was supported by both regulators and industry, to develop a revised method and initiate a ring test of an improved OECD 306 test. The goal is to improve the current OECD 306 marine biodegradability test to enable this to provide a more robust and effective prioritisation screen for marine persistency of chemicals used offshore or likely to enter the marine environment. A summary of the workshop discussions together with the key features of the improved test and status of the OECD 306 ring test will be presented.

TH002
Biodegradation of both chlordecone and degradation products resulting from chemical treatment
a. Mauffret, BRGM / Environmental biogeochemistry and water quality; S. Bristeau, BRGM / Division Laboratoires; C. Mouvet, BRGM
Chlordecone (CLD: $C_{10}Cl_{10}O$) is an organochloride insecticide used to control the banana weevil from 1972. Even its withdrawal in 1993, CLD is still present in drinking water and food crop products and impacts on human health have been documented since 2001. In soils, concentrations up to 15 mg/kg have been reported which also stress its high persistency. The depollution process of In Situ Chemical Reduction (ISCR) tested in laboratory conditions by BRGM enabled to reduce by 60-70% the CLD concentration in soil. It has successfully gone through a pilot test in a banana field in martinqiue (French west Indies). This process breaks down the parent molecule in dechlorinated molecules (mainly mono, di and tri-hydro CLD), for which ones it could be hypothesized that bioaccessibility via the dechlorinated region of the molecule may be facilitated as compared to the parent molecule. We have selected various inocula, based on their historical exposure to CLD, ability to degrade other highly chlorinated compounds (PCB…), or high bacterial activity. Their ability to degrade CLD and dechlorinated CLD was tested in feed-batch systems spiked with CLD and tri-hydro-CLD, for which ones we have standards in sufficient quantity to run such tests; synthetises of purified dechlorinated CLD still being a challenge. We have a methodology based on liquid extraction and GCMS to quantify simultaneously the parent compound and several of its metabolites to ensure distinguishing loss by sorption from degradation in the feed batches with solid support on which one the highly hydrophobic compounds can sorb on. Very preliminary results after 7-month incubation did not point out a clear distinction between biodegradation kinetics for CLD and the tri-hydro CLD. We also observe a biodegradation product for CLD resulting from the opening of carbonated cage of the molecule ($C_9Cl_5H_3$), which ones biodegradation steps are still unclear. Biodegradation tests are undergoing.

TH003
Improvement of Bioavailability for Substances with low water solubility in Ready Biodegradability Tests
S. Fiebig, DR.U.NOACK-LABORATORIEN; H. Maischak; U. Noack, DR. U. NOACK-LABORATORIEN
Often substances fail the criterion for ready biodegradability or an unequivocal assessment is not possible because the substance is not bioavailable for the degrading bacteria due to its low water solubility. As the biodegradation of a substance strongly depends on its mass transfer and the bioavailability for the degrading bacteria, there are several technical issues which need to be addressed while testing the biodegradability of poorly water soluble substances. Due to the historic background of the guidelines for testing ready biodegradability the test concentration is relatively high (2 – 100 mg/L) and not reflecting environmental concentrations. To improve the bioavailability of poorly water soluble substances in tests for ready biodegradability the application technique and the agitation during testing need therefore special consideration. Careful investigation of the application method prior to the test start can enhance the degradation distinctly. Four techniques for the application of poorly water-soluble substances are commonly used and described in the ISO standard 10634 (1995) and recommended by the REACH guidance. These methods are direct addition, ultrasonic dispersion, adsorption onto an inert support material and the use of non-biodegradable emulsifying agents. So far no single method is recommended and routinely a combination of approaches is used for application. Based on the substance properties the application method has to be chosen carefully. These investigations involve a relatively small extra effort and often more expensive simulation studies can be avoided. The influence of different application techniques on the bioavailability and biodegradation of poorly water-soluble substances was investigated and the results will be presented.

TH004
BIODEGRADABILITY OF THE ANIONIC SURFACTANT SODIUM LAURYL ETHER SULPHATE IN INDUSTRIAL PRODUCTS
L. Patrolecco, Water Research Institute-National Research Council / Water Research Institute; N. Ademollo, National Research Council of Italy / Water Research Institute; M. Cardoni, Italian National Research Council / Water Research Institute; P. Grenni, National Research Council of Italy (CNR) / Water Research Institute; G. Mininni, J. Rauseo, Italian National Research Council / Water Research Institute; A. Barra Caracciolo, National Research Council of Italy / Water Research Institute; T. Pescatore, National Research Council / Water Research Institute
Anionic surfactants are widely used in numerous commercial (e.g. personal care products) and industrial products (e.g. foaming agents for drilling cavities in subterranean formations). The construction of tunnels with mechanized drills produces a large amount of debris rich in foaming agents, added during the excavation process, that have an impact unknown on ecosystems. The lack of accurate information about the environmental impact of these excavated rocks has aroused increasing concern for their possible recycling as construction materials or as soil replacement for covering rocky areas. The objective of this study was to

evaluate the biodegradability of the anionic surfactant sodium lauryl ether sulfate (SLES) contained in two commercial foaming agents. For this purpose, a set of microcosms was set up using two different soils treated separately with one of the two commercial products at the concentrations used for the mechanized drill. At selected times (0, 7, 14, 21, 28 d) soil samples were collected for assessing SLES concentrationby MBAS spectrophotometric method. Moreover, microbiological analysis were performed in order to assess microbial abundance, cell viability and dehydrogenase activity. An initial negative effect on microbial abundance and viability was observed, although it was transient. At the end of the experiment SLES was no longer present in all soils and the dehydrogenase activity and cellular vitality were comparable between treated and control soil.

TH005
Effect of Different Inocula in Biodegradation Tests
C. Mead, N. Best, Envigo Research Limited / Ecotoxicology Department
In the assessment of the biodegradability of organic substances, the role of the inoculum in a successful outcome is often overlooked. Despite ready biodegradation Test Guidelines (OECD, OPPTS) allowing the use of a variety of inoculum sources such as activated sewage sludge, sewage effluents, surface waters and soils, or a mixtures of these, typically in ready biodegradation tests a single inoculum source such as activated sewage sludge is employed. In the consideration of persistency, European Chemicals Agency (ECHA) guidance for the performance of enhanced biodegradation tests acknowledges that procedures that maximise diversity and adaptation of microbial populations in the test system are required. The work presented assesses the impact of different inoculum sources and inoculum concentration, along with the effect of mixed inoculum sources on the biodegradation of typical organic substances. Biodegradation was assessed using the OECD 301B “CO_2 Evolution Test” method referenced as EPA Fate, Transport, and Transformation Test Guidelines OPPTS 835.3110 (Paragraph (m)).

TH006
OECD 306 and Marine BODIS biodegradation tests
K. Wadhia, Opus / Environmental; S. Finn, Fjords Processing / Environmentall; R. Garrioch, Fjords Processing; J. Laud, Fjords Processing / Environmental
Each method has particular limitations which may reduce the biodegradation of materials tested or the suitability of the test method for the test substance properties. Assessment implemented will be conveyed of the suitability of the methods for biodegradation testing of water soluble organic substances and poorly water soluble / water insoluble organic substances in seawater. Unlike similar screening tests for biodegradability in freshwater systems, the marine method employs no separate bacterial inoculum, and relies upon populations of bacteria which occur naturally in seawater. The test serves only to provide a preliminary level of information on ready degradability in seawater. The overall assessment of biodegradability is based upon a comparison between experimentally determined oxygen consumption (BOD measurements) and the oxygen consumption predicted if all carbon present in the test material were completely oxidised (theoretical oxygen demand, ThOD). Where the composition of the test material is known, or can be reasonably inferred, the ThOD can be calculated from the empirical formula and the molecular weight. If neither the empirical formula nor chemical composition of the test material can be obtained, then the prediction of maximum potential BOD is obtained from the determination of the chemical oxygen demand (COD) or CHN analysis. The implications of reliance upon populations of bacteria which occur naturally in seawater rather than introduced inoculum, and the shortfalls of the procedures and scope for improvement are examined from testing and regulatory perspectives. **OECD 306, Biodegradation, BODIS**

TH007
Application of chemostat systems to include adaptation of microbial communities in persistency testing (CEFIC-LRI Eco29, University of Amsterdam)
B.A. Poursat, University of Amsterdam/IBED Institute / Institut for biodiversity and ecosystem dynamics; J. Parsons, University of Amsterdam / IBED; W. Röling, Vrije Universiteit Amsterdam / Faculty of earth and life sciences; P. de Voogt, University of Amsterdam / IBED
The aims of this CEFIC-LRI Eco29 project is to study the microbial adaptation to persistent chemicals using continuous culture systems, in order to develop guidelines for persistency tests in which the role of adaptation is accounted for. Because of its origin and history, the microbial inoculum is source of variability in biodegradability assessment. In OECD’s biodegradation testing, the short exposure times do not allow for adaptation of microbial communities to a new chemical, while in the natural environment, microorganisms tend to adapt to pollutants upon long term exposure. Which might significantly affect the results of biodegradation assessment, and might lead to the degradation of chemicals that were initially persistent. Despite numerous publications demonstrating the impact of adaptation on biodegradation test results, microbial adaptation is not include in the guidelines. Nevertheless, the importance of the adaptation phenomena in assessing biodegradability should not be underestimated. Continuous culture systems offer excellent opportunities to allow microorganisms to adapt to new chemicals under defined and environmentally relevant conditions parameters, for in theory, infinite periods of time. For our first step, environmental microbial communities (e.g. wastewater communities) are exposed to carbamazepine (CBZ) for a long term and under defined conditions, in order to follow its biodegradation and its impact on community structure and on microbial genome. Furthermore, variation of growth conditions in culture could lead to an understanding of their importance in the adaptation process. Results of this experiment will allow us to a better understanding of the relationship between microbial adaptation and biodegradation outcome and will ultimately facilitate the design of more robust screening studies and enable better predictions of biodegradation.

TH008
The impacts of light and season on isopyrazam degradation in river microcosms
R. Southwell, University of Warwick; L. Hand, Syngenta Limited / Product Metabolism; J. Pearson, University of Warwick / School of Engineering; G. Bending, University of Warwick / School of Life Sciences
Industry uses tests provided by the Organisation of Economic Cooperation and Development (OECD) to assess the potential for transformation of a chemical and its metabolites in the environment, before it can be approved for use. Various factors are important in determining chemical fate in the environment, but many are not considered in initial laboratory tests. In particular, light can be a major influence on microbial abundance, but these tests are carried out in the dark. Additionally, microbial community abundance and diversity are likely to change in time in relation to water quality and climate, but there is little consideration of time of year that sampling takes place. We investigated the impact of light on the transformation of ^{14}C-isopyrazam, a fungicide, in river microcosms, using water and sediment collected at defined seasonal time points across an 18-month period. Materials were collected from the River Dene (Wellesbourne, UK), and both water and water-sediment microcosms were pre-incubated in the dark or light (18 hour light/6 hour dark cycle) for 9 days prior to isopyrazam addition (0.1 mg/L). There was little degradation of isopyrazam in dark microcosms regardless of season. However, in microcosms incubated under a light-dark cycle, degradation was faster in all seasons, although the rate of degradation varied depending on time of year sampling took place. Microcosms sampled in autumn or summer gave the fastest degradation rates, whereas microcosms containing samples collected in winter gave the slowest degradation rate. This trend was seen in both the water and water-sediment microcosms, although there was a greater effect in water-sediment systems. There were also differing degrees of mineralization across time, but the extent of mineralization was not correlated with the overall isopyrazam degradation rate. To date, microbial community analysis has focused on phototrophic communities using chlorophyll *a* abundance as a measure. While phototrophs appear to be important determinants of isopyrazam degradation, overall abundance of phototroph communities was not closely related to differences in degradation of isopyrazam across time. This suggests that phototroph community composition, or interactions between phototrophs and other taxa, could underlie temporal variations in isopyrazam degradation.

TH009
Multiple use of vegetation in dioxin contaminated soil
J. Wittebol, M.H. Wagelmans, E. Elferink, Bioclear
There is an ongoing global and socially relevant transition towards biobased production processes. Biobased production processes use renewable resources from the living environment (biomass, green materials) as part of the sustainable economy. Due to long term and widespread use of POP’s for example PCB’s, PAH or dioxins soils can be polluted with these chemicals. This might result in pollution of renewable resources. The sugar beet for example is a versatile product. It is used to produce sugars, molasses and pulp. These sugars are sequentially used in foods, biofuel or PET + PEF bottles. PAH is detected in molasses and dried sugar beet pulp. Dioxins, PAH and PCB’s are lipophilic organic compounds and are more prone to absorb to the root or soil particles than being taken up by root into the inner root and for transport into the rest of the plant. There are however exceptions. The goal of this research is to investigate possibilities to connect the biobased production with the removal strategy of POPs from soil. The possibility of composting PCDD, PCB’s and PAH contaminated biomass was investigated in both aerobic as well as anaerobic digested systems. When organic waste streams are contaminated with POP’s the toxicity might be affected by additional processes for example biological degradation. This could either be positive or affect the process negatively. And thus the application of contaminated waste should be considered in detail. With the application of the (possibly) contaminated renewable resources the value of the agricultural land as well as the “agricultural waste” can be increased. It is unknown if biorefinery production processes are affected by persistent contaminants like dioxins. The main question is which processes occur both during uptake and during biobased refinery. What does this mean for the final product and possible waste streams? And can “pollution” of the end product be prevented by additional processes in soil and during refinery?

TH010
Risks of Non Extractable Residues (NER) of chemicals in soil
J. Harmsen, Alterra, Wageningen-UR / CALM; D. Hennecke, Fraunhofer IME -

Institute for Molecular Biology and Applied Ecology / Ecological chemistry; K. Hund-Rinke, Fraunhofer IME; J. Lahr, Alterra; J.W. Deneer, Alterra Wageningen UR / ERA team

With regard to regulation of chemicals, Non Extractable Residues (NER) are considered as an increasingly important issue. Depending on the stakeholders, NER is considered in two ways, either as a chemical time bomb or as a sustainable way of detoxification. ECETOC has provided a proper basis for our study with ideas on extraction regimes and tests to access the risks. In our study we investigate three substances that are known to give a Non Extractable Residue; TNT, Cypermethrin and Carbendazim. In our chemical approach we distinguish the measurable parameter Total concentration (harsh extraction) and the bioavailable concentration as can be measured with Tenax or in the water phase. Bioassays are used two follow the change in toxicity during aging and the probable formation of NER. By selective extraction of the bioavailable fraction, toxicity should decrease. The investigation of the validity of this assumption is an important part of our study. It is not possible to measure NER under normal conditions. Radiolabelled versions of the chemicals are necessary to establish the fate of the chemical. Residual radioactivity after extraction is considered to be the result of formation of NER. This can be caused by a very strong binding of the chemical, but also by inclusion of the radiolabel in the biomass or carbonates or inclusion of intermediates of degradation. In our study we have followed radioactivity in the spiked and aged soils using three different and representative soils Our study aims to provide a clear, mechanistically driven definition for NER and residual toxicity caused by NER. As stated by Ortega-Calvo et al. (2015) this should be measurable in order to have a clear function in regulation. For this purpose we develop a “soup test” to assess the toxicity of the different fractions of chemicals.

TH011

Ready biodegradability of poorly water-soluble substances: an evaluation strategy proposal

C. Sweetlove, lOREAL SA / Research and Innovation; J. Chenèble, LOreal Research; Y. Barthel, EUROFINS / Eurofins Expertises Environnementales; T. Gerald, University of Nantes / Microbiology; J. Lharidon, LOREAL / Life Sciences Direction

Biodegradability is a key parameter in several international regulations on chemical substances, such as the European Union REACH and CLP regulations. In order to evaluate the complete mineralisation of chemicals, i.e. ultimate biodegradation, tests have been designed under the umbrella of international organisations such as the OECD (Organisation for Economic Co-operation and Development) and ISO (International Organisation for Standardisation). Among these tests, the ready biodegradability tests (RBTs) enable an assessment of the ultimate biodegradability in aqueous media under aerobic conditions, but only few guidance documents have suggested technical adaptations to improve the bioavailability of poorly water-soluble chemicals. In this context, the aim of this study is to develop a two-phase evaluation strategy to select the most relevant Bioavailability Improvement Methods (BIMs) for enhancing the biodegradability of tested substances. Tests were performed with a solid (Anthraquinone) and a liquid (Isodecyl Neopentanoate) substance versus 5 BIMs: i) ultrasonic dispersion, (ii) dispersion using an emulsifier, (iii) adsorption onto silica gel, (iv) dispersion with silicone oil, (v) dispersion with an emulsifier and silicone oil. The calculation of a BIM classification index is proposed, which enables the ranking of the different operating conditions.

TH012

New biodegradation tests for chemical compounds at low environmental relevant concentrations

B. Ozel, University of Lausanne / Fundamental microbiology; S. Beggah, University of Lausanne; S. Rey, M. Seyfried, Firmenich / Biotechnology; J. van der Meer, University of Lausanne / Department of Fundamental Microbiology

Existing biodegradation methods such as OECD tests are typically carried out at relatively high substrate concentrations such as 20 mgC/L that may result in under- or over- estimation of observed substrate utilization kinetics at environmentally relevant low concentrations. Furthermore, although well established, OECD guidelines are largely not suitable for testing hydrophobic and volatile compounds such as fragrances. Our main goal is to develop a standardized and validated growth-linked biodegradation test as an alternative method to existing biodegradation tests? in the range of 0.1 - 10 mgC/L. Our methodological concept is based on comparative evaluation of cell density measurement by flow cytometer and substrate disappearance measurement by CO2 evolution and gas chromatography under assimilable organic carbon restricted conditions. We conduct our experiments with lake water microbial communities at starting cell density of 10E4 and 10E5 cells/mL in a defined mineral medium. Sodium benzoate, 1-octanol, anthraquinone and phenol are selected as primary positive controls for readily biodegradable compounds. We observed step-wise increase in the lake community size (at initial cell density of 10E4 cells/mL) at the expense of added positive control substance at concentrations of between 0.1 – 2 mgC/L and 1–2 mgC/L, respectively. Yield approximations from the observed community growth was in line with CO2 evolution test results for the target compounds. For accurate mass balance between compound and community size, we will further simultaneously measure lake water community growth and compound disappearance by gas chromatography. Lake water communities that enable biodegradation of the test compounds will be analyzed for diversity changes, and we will also further isolate and characterize degrader bacteria. **References:** Czechowska K, Sentchilo V, Beggah S, Rey S, Seyfried M, van der Meer JR. Coupling traditional biodegradation assessments with spectroscopic tools for plastic wastes: case of Polyurethane wastes assessment

M. Cregut, University of Nantes / GB; M. Durand, University of Nantes / UMR CNRS GEPEA CEBAC Laboratory; A. Assaf, University of Nantes / GEPEA CNRS UMR CBAC Laboratory; T. Gerald, University of Nantes / Microbiology

Development of new strategies to assess chemicals fate is needed. Among the diverse family of chemicals, synthetic plastic wastes are of great concerns due to their robust accumulation in landfills, which is estimated to account for 10 to 30% (w/v) of total wastes in landfills (in USA and in Japan). Strategies to assess the biodegradability of these polymers are generally complex and limited in their efficiency, because they are confronted to a mixture of chemicals having each one their own intrinsic properties in terms of solubility, toxicity and persistence. To assess the biodegradability of a polyurethane waste generated by an industrial, we’ve attempted to develop a strategy based on traditional assessments for toxicity and biodegradation (carbon balance) coupled with the Raman spectroscopy to evaluate both quantitatively and qualitatively changes occurring during the polymer waste biodegradation. The carbon balance analysis enables to identify polyurethane compartmentalisation after the microbial biodegradation: 0.5% of the carbon has been converted in biomass, 3.9% was released as inorganic carbon and 23.2% as volatile organic carbon. The majority of the carbon (72.5%) remains as polyurethane powder after the biodegradation event. To evaluate the impact of the microbial inoculum onto the chemical structure of the polyurethane, spectral analyses were done. Some major changes have been operated in the chemical structure of the polymer as the disappearance of certain peaks corresponding to ether (1,181 cm^{-1}) and aromatic C-C bonds (1,520 cm^{-1}). According to the untreated polyurethane analyses, it appears that the polymer structure is deeply altered and that its polyether fraction has been degraded by the inoculum. To conclude, coupling the traditional assessments methods and the spectroscopic profiling enabled to characterise how the polymer is affected by the inoculum. Although the polyurethane was degraded only at 27.5%, a deep change in its chemical structure was operated leading notably to the disappearance of some rich region composed of high content of polyethers. This assessment strategy appears to be relevant to better understand in a quantitative but also in a qualitative manner how the synthetic plastics can be altered by microorganisms. Keywords: Biodegradation, Polyurethane biodegradation, Raman spectroscopy, carbon balance, inoculum adaptation

Exploring links between the biodegradation of chemical contaminants, the metabolic capability of microbial communities and environmental variables (P)

Effects of agricultural practices on organic matter degradation in ditches

E.R. Hunting, CML Leiden University; J. Vonk, University of Amsterdam IBED Institute; K.J. Musters, Leiden University / Institute of Environmental Sciences; M.H. Kraak, University of Amsterdam IBED Institute / Aquatic Environmetal Ecology; M.G. Vijver, CML Leiden University

Detritus processing relies on the quantity and quality of dead organic matter available as food for the detritivorous community and is essential to global carbon and nutrient cycling. Agricultural practices have direct adverse effects on biodiversity, but also can differentially affect the input of terrestrial organic matter (OM) sources and agricultural chemicals into adjacent aquatic ecosystems. Hence, agricultural practices potentially affect OM quality and inherent decomposition by microorganisms and consumption by invertebrates in adjacent agricultural drainage ditches. This study therefore aimed to determine the effect of agricultural practices on OM degradation by microorganisms and invertebrates in agricultural drainage ditches. A consumption and food preference experiment was performed in the field and in the laboratory using natural OM collected from the field that reflects the agricultural practices ‘dairy farm grasslands’ and ‘hyacinth bulb fields’, in which freshly cut grass and hyacinths were also offered to control for OM composition. Large- and small mesh-sizes were used to distinguish microbial decomposition and invertebrate consumption. Results showed that OM collected from ditches adjacent to grasslands and freshly cut grass and hyacinths were preferred over OM collected from ditches adjacent to hyacinth bulb field, in which both microbial decomposition and invertebrate consumption were strongly retarded. This is likely the result of sorption and accumulation of pesticides, rendering sediment OM unsuitable for microbial decomposition and invertebrate consumption. This outcome illustrates that differences in agricultural practices can, in addition to direct detrimental effects on aquatic organisms, indirectly alter the functioning of adjacent aquatic ecosystems.

TH015

Fullerol as a potential pathway for mineralisation of fullerene nanoparticles in biosolids-amended soils

D.G. Navarro, CSIRO / Environmental Contaminant Mitigation and Technologies; R.S. Kookana, CSIRO / Land and Water; M. McLaughlin, CSIRO/University of Adelaide / University of Adelaide and CSIRO Land and Water Flagship; J. Kirby, CSIRO / Advanced Materials Transformational Capability Platform Land and Water

Fullerenes (e.g. $C_{60,}C_{70}$) nanomaterials are now used in a wide range of products and thus can enter the environment via waste streams. Although these contaminants could reach and potentially adversely affect the terrestrial environment via the re-use of biosolids, their fate in soil is poorly understood. This study examined the mineralisation of C_{60} and its transformation product fullerol (C_{60}-OH with drastically different physico-chemical properties) in biosolids-amended soils. Using radiolabelled C_{60} and C_{60}-OH, we established that mineralisation of C_{60} was less than the detection limit (< 0.025%) in three contrasting soils during a 55 day long experiment. In contrast, however, up to 3% of C_{60}-OH was mineralised during this period. This difference in observed mineralisation highlights C_{60}-OH's greater bioavailability compared to its parent compound, C_{60}, in biosolids-amended soils. These results indicate that transformation of certain fullerenes, such as to fullerol, could provide a potential pathway for their mineralisation, but such transformation may be slow. Glucose-induced respiration tests on C_{60}-/ C_{60}-OH contaminated soils suggested that overall microbial activity was not compromised by the contamination. This study is also the first work to examine the fate of fullerol in soils.

TH016

Kinetics of rapid covalent bond formation of aniline with humic acid: ESR investigation with nitroxide spin probes

K. Glinka, University of Osnabrueck / Department of Physics; M. Matthies, University of Osnabrueck / Institute of Environmental Research; K. Hideg, University of Pécs / Organic and Medicinal Chemistry; H. Steinhoff, University of Osnabrueck / Physics

The bioavailability of many soil and sediment contaminants depends on their interaction with the organic matrix. In biodegradation simulation studies, many of these xenobiotic chemicals exhibit a large fraction of residues, which cannot be further extracted even by harsh methods (non-extractable residues, NER). The paper presents a new approach of using stable paramagnetic spin probes for investigating the kinetics of covalent binding of xenobiotic functional groups with humic acids, the main organic matter fraction. Leonardite humic acid (LHA) was incubated with the nitroxide spin label Anilino-NO (2,5,5-Trimethyl-2-(3-aminophenyl)pyrrolidin-1-oxyl), which includes an aniline functionality susceptible to interaction with LHA. ESR spectra of LHA samples were recorded at X-band frequency (9.43 GHz) at room temperature. A broadened ESR signal was observed of Anilino-NO incubated with LHA, which indicates strong restriction of the reorientational motion of the spin probe, i.e. immobilzation due covalent binding of the aniline group. This signal increased immediately after incubation and was used to determine the kinetics of the covalent bond formation. A two-sites model with two parallel first-order reactions was used for fitting the measured values and determining the rate constants. A fast reaction with a rate constant of 0.308 min^{-1}, i.e. a half-life of approximately 2.25 min, and a slower reaction with a rate constant of 0.012 min^{-1}, i.e. a half-life of 57.8 min, was observed. Laccase-treated LHA shows an increase of the amount of reactive sites, presumably quinones, by a factor of 7.2 for the slow reaction, which supports the conclusion of a nucleophilic addition reaction of the aniline moiety with LHA. Both reaction rate constants are only marginally enhanced for the laccase-treated LHA. Paramagnetic spin probing is an effective method to investigate the rapid formation of covalent binding of xenobiotic functional groups humic acids. For chemicals containing an aromatic amino group a considerable fraction of NER can be explained as covalently bound residues, which is important for the determination of persistence in soil and sediment required for PBT and risk assessment of pesticides, biocides and other chemicals.

TH017

Fate, biodegradation and mineralization of two labeled pesticides in soils under different environmental conditions

A. Muskus, UFZ Center for Environmental Research / Department Umweltbiotechnologie; M. Kästner, Helmholtz centre for environmental research - UFZ / Department of Environmental Biotechnology; U. Hamer, WWU - University of Muenster / Institute of Landscape Ecology; K. Nowak, RWTH Aachen University / Institute for Environmental Research Biology V

Objectives of the Study To study the turnover mass balance (CO_2 evolution, extractable contaminant residues and non-extractable residues) of ^{13}C-labeled 2,4-D and ^{13}C, ^{15}N-labeled Glyphosate in soils under different environmental conditions. To investigate the incorporation of ^{13}C-label into microbial fatty acids, and $^{13}C^{15}N$-labels into amino acids from ^{13}C-labeled 2,4-D and $^{13}C^{15}N$-labeled Glyphosate in soils. To quantify the extent of "biogenic residues" formation during the degradation of two pesticides under different environmental conditions. To define how the environmental conditions (e.g. temperature, soil organic matter and soil pH) the biodegradation of pesticides and the extent of "biogenic residues" formation. **Material and Methods** Soil samples were collected from the 0 to 5 cm soil layer in the agricultural field located in Bad Lauchstädt, Germany. The soil organic matter (OM) of the soil and the pH were modified reaching 3%OM and 4%OM and pH 5.5 and 6.0, accordingly. Thereafter, soil was spiked with a labeled pesticide (^{15}N-$^{13}C_3$-Glyphosate or $^{13}C_6$-2,4-D) and incubated according to the OECD 307 and at different temperatures (10°C, 20°C and 30°C). The $^{13}CO_2$ evolution was quantified by Inorganic Carbon Analyzer and the isotopic composition was measured by GC-IRMS. After the incubation, the residual parental pesticide + its primary metabolites and microbial biomass components (amino acids) were extracted and quantified and identified using UHPLC (Glyphosate) or GC-MS (2,4-D, amino acids) and the isotopic composition was measured by GC-IRMS. **Results** After 39 days of incubation, mineralization of $^{13}C_3$-glyphosate in soil containing 3%OM, 4%OM and pH 6 at 10°C, 20°C and 30°C was higher than 20%, 45% and 50%, respectively. In the same experiment with soil at pH 6 and pH 5.5 at 10°C, 20°C and 30°C the mineralization of glyphosate was lower and reached about 16%, 35% and 40% of $^{13}C_3$-glyphosate equivalents, respectively. Mineralization of $^{13}C_6$-2,4-D in soil containing 3%OM after 32 days of incubation constituted more than 18%, 50% and 70% of $^{13}C_6$-2,4-D equivalents at 10°C, 20°C and 30°C, respectively. In the soil at lower pH (5.5 and 6), mineralization of this herbicide was lower and reached accordingly 2%, 20% and 20% at 10°C, 20°C and 30°C. **Conclusion** The first results showed a positive influence of the environmental conditions like temperature and OM content of soil on the extent of glyphosate and 2,4-D mineralization in soil.

TH018

Identification of biotransformation products of the herbicide Imazapic via suspect screening

M. Majewsky, Karlsruhe Institute of Technology KIT / Engler Bunte Institut Chair of Water Chemistry and Water Technology; S. Merel, C. Zwiener, Eberhard Karls Universität Tübingen / Environmental Analytical Chemistry Center for Applied Geosciences; H. Horn, Karlsruhe Institute of Technology KIT / EnglerBunteInstitut Chair of Water Chemistry and Water Technology

Imidazolinones are selective herbicides used in weed control of agricultural areas. These substances persist in soils with half-lives of up to 233 days and some of these compounds have been prohibited in European countries. While a number of studies focused on their ready photochemical transformation, far less is known about their microbially mediated transformation pathways in aquatic systems. Compared to the clean matrix of aqueous photolysis experiments, the identification of biotransformation products is much more challenging. The present study tested the susceptibility of the imidazolinone imazapic (IMA) to microbial transformation in order to elucidate the formed transformation products. An activated sludge inoculum was used for spiked batch experiments and regularly fed with additional primary substrate. After a total runtime of eight days, 23 % of IMA was transformed. In a first step, we screened samples for 90 previously defined suspected transformation products using LC-Q/TOF accurate mass scans. Six suspect transformation products could be matched by their precursor *m/z* with a mass accuracy of < 2 ppm. Subsequently, MS/MS spectra were recorded and interpreted to confirm the suspected compounds. Further structural product ion elucidation also allowed for indication of the transformation site on the molecule. In this way, decarboxylated-IMA, hydroxylated-IMA, demethylated-IMA and *N*/*O*-methylated-IMA could be identified as biotransformation products. The detected TP293 is tentatively assigned to a product hydroxylated at a double bond (elemental mass shift of H2O), possibly a ring opening reaction. A further product, TP276, indicated NH substitution by an OH moiety, but requires further confirmation. The results indicate preferential microbially mediated transformation reactions at specific sites on the molecule, which can be further used as model for other imidazolinones with similar structures.

TH019

Biodegradation of synthetic β-triketone herbicides

S. Romdhane, University of perpignan / CRIOBE BAE; M. Devers-Lamrani, INRA Institut National de la Recherche Agronomique / UMR Agroecologie; F. Martin-Laurent, INRA / Agroecologie; J. Cooper, University of perpignan / CRIOBE; C. Calvayrac, University of perpignan / BAE; l. barthelmebs,

Agricultural use of pesticides ensures a higher crop quality and production but it is also one of the major sources of diffuse pollution in the environment. Microbial degradation is considered as an important dissipation process limiting the accumulation of pesticides in the environment. In this context, two bacterial strains able to degrade sulcotrione, a β-triketone herbicide, were isolated from an agricultural soil previously exposed to this herbicide. The two isolates were identified using 16S rRNA gene sequencing as *Pseudomonas sp.* 1OP and *Bradyrhizobium sp.* SR1. Their capacity to degrade aerobically sulcotrione was estimated and 2-Chloro-4-mesylbenzoic acid (CMBA), one of its main metabolites, was clearly detected. Their ability to degrade other β-triketone herbicides was tested showing that only *Bradyrhizobium sp.* SR1 was able to completely degrade another β-triketone herbicide, mesotrione and producing already known metabolites (AMBA and MNBA). Microbial toxicity of sulcotrione and mesotrione and their related metabolites in bacterial cultures was estimated by monitoring 4-hydroxyphenylpyruvate dioxygenase (HPPD) enzyme inhibition. Our results indicate that β-triketone herbicides toxicity linked to HPPD inhibition was due to parent molecules, and not to the formed metabolites. Attempts were done to identify the genetic localization of sulcotrione degradation in *Pseudomonas sp*. 1OP and *Bradyrhizobium sp*. SR1. Plasmid profiles of both strains revealed the presence of large plasmids (>12 kb and >50 kb, re*sp*ectively). Curing experiments showed that *Pseudomonas sp*. 1OP lost its ability to degrade sulcotrione under non-selective conditions, therefore degradation capacity may be attributed to the presence of this plasmid. On the contrary, under the same conditions, *Bradyrhizobium sp*. SR1 plasmid was not cured and the sulcotrione-degrading ability of the strain was maintained. Furthermore, a 14 000 Tn*5* mutant library was constructed using a Tn*5* mutagenesis approach conducted on *Bradyrhizobium sp*. SR1. Among this library, two mutants affected in their biodegradation capacity were identified. Full sequencing of SR1 and Tn*5* mutants is ongoing to identify possible degrading gene candidates. Keywords: biodegradation, β-triketone, herbicides, metabolites.

Fingerprinting Micropollutant Transformation in Hyporheic Zones

M. Posselt, Stockholm University / Department of Environmental Science and Analytical Chemistry; A. Ribbenstedt, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; J. Benskin, Stockholm University / Environmental Science and Analytical Chemistry

Hyporheic zones are key compartments for the functioning of aquatic ecosystems. As dynamic and complex transition regions between rivers and aquifers, they are characterized by the simultaneous occurrence of multiple physical, biological and chemical processes. Assessing persistence of environmental contaminants in the hyporheic zone is non-trivial. In addition to advection processes, transformation can be influenced by numerous biogeochemical factors, including physical characteristics of the sediments (e.g. porosity and bed morphology), chemical parameters (e.g. occurrence of electron donors or acceptors), and biological factors (number and type of microbial population). These variables can lead to difficulties in reproducing lab-based biodegradation experiments and in extrapolating estimates of persistence in the lab to field conditions. Benchmark chemicals (i.e. model substances which are co-incubated with a substance of interest in lab-based biodegradation experiments) have been proposed as a means of addressing inter-assay variability in sediment biodegradation experiments. These controls may aid in extrapolating amongst various lab-based experimental designs and conditions, and perhaps even to conditions encountered in the field. The present work takes an initial step towards characterizing a suite of benchmarking chemicals for use with sediment biodegradation experiments by measuring their degradation half-lives ($DegT_{50}$) under a series of carefully controlled conditions (temperature, oxygen content, stirring) in closed-bottle experiments. Natural sediments from the river Erpe (Berlin, Germany) were collected and characterized prior to use. Marker chemicals (which included pharmaceuticals and industrial chemicals) were selected based on their environmental occurrence and to cover a range of physicochemical properties, transformation rates and pathways. We expect this approach to aid in the development of more appropriate assays specifically designed for probing micropollutant transformation in the hyporheic zones, for extrapolation of micropollutant half-lives between lab and field, as well as among diverse river sediments and within various locations within a river system.

TH021

The role of solar radiation on the photodegradation of PAHs in soils

M. Marques, Rovira i Virgili University / Chemical Engineering; N. Domínguez, URV/IISPV; M. Mari, Rovira i Virgily University / Chemical Engineering; J. Sierra, Universitat Rovira i Virgili / Soil Science Unit; M. Schuhmacher, Rovira i Virgili University / Chemical Engineering; M. Nadal, University Rovira i Virgili / Laboratory of Toxicology and Environmental Health; J.L. Domingo, Universitat Rovira i Virgili / Laboratory of Toxicology and Environmental Health

Polycyclic aromatic hydrocarbons (PAHs) are a family of widespread environmental pollutants, whose chemical structure is based on two or more fused benzene rings. PAHs are released from natural and anthropogenic combustion processes. Although these chemicals are mostly released to air, soil is considered as one of the major sinks of atmospheric PAHs, undergoing wet and dry deposition processes. Since the environmental fate and transport of PAHs is highly influenced by temperature and solar radiation, photodegradation is likely to be the main process related to the loss of PAHs on soil surfaces, leading to the potential formation of more toxic metabolites than their parent compounds. This study was aimed at estimating the photodegradation rate of PAHs in soils under winter conditions in the Mediterranean region. Soil samples were taken from the A horizon of two common Mediterranean soils located in remote areas. Arenosol soil samples corresponded to Haplic Arenosol, an acidic and coarse-textured soil with granitic origin. In turn, Regosol soil samples belonged to Calcaric Regosol, which is formed of sedimentary materials and fine-textured soil. Ten grams of cleaned soil were deployed in uncovered glass Petri dishes. Every sample was spiked with 250 μL of a stock solution containing 16 US EPA priority PAHs at a concentration of 100 μg/mL and exposed to sunlight radiation in a methacrylate box placed on the roof of the School of Chemical Engineering, Tarragona, Catalonia. Dark controls were also performed to assess slow sorption processes. Temperature and solar radiation intensity were simultaneously monitored over the experiment. The results showed that PAHs behaved differently according to their molecular weight, temperature, radiation and soil texture. A decreasing trend of PAH concentrations in both soils in samples exposed to daylight was observed. Low molecular weight PAHs are more influenced by volatilization and sorption, while photodegradation is more evident for medium and high molecular weight PAHs. Photodegradation rates were higher than those obtained previously in laboratory conditions, since the intensity of solar radiation is ten times higher than that emitted by fluorescents in a climate chamber.

TH022

Bioavailability-related effects of dissolved organic matter on biodegradation of PAHs

J. Ortega-Calvo, Instituto de Recursos Naturales y Agrobiologia / Agroquimica y Conservacion del Suelo; C. Jimenez Sanchez, Inst de Recursos Naturales y Agrobiol. de Sevilla / Agroquimica y Conservacion de Suelos; R. Posada-Baquero, J. Garcia, M. Cantos, Instituto de Recursos Naturales y Agrobiologia de Sevilla CSIC

In environmental sciences, dissolved organic matter (DOM) is usually differentiated from particulate organic matter as the size fraction of organic matter smaller than 0.45 μm. This fraction typically consists of a multitude of structurally different compounds, all typically present at low concentrations, although it can differ significantly in quality (or biodegradability) and quantity in time and space. The environmental fate of organic pollutants, such as PAHs, can be affected by DOM via increased apparent solubility, desorption, transport and biodegradation. In our group, we have specifically addressed the influences of DOM quality on bioavailability-related phenomena: chemotaxis, attachment and solubilisation. We used, for our studies, different experimental models to assess the bioavailability of PAHs for biodegradation, and these included Tenax extraction, dual 14C/residue analysis of microcosm samples, dynamic passive dosing with PDMS, biphasic NAPL/water systems, and column systems. Different model DOM sources, of dissimilar quality but all with potential use in bioremediation were used, and included humic acids, root exudates, biosurfactants and organic fertilizers. We found that biodegradation of poorly bioavailable PAHs was enhanced by (bio)surfactants (Environ. Sci. Technol. 48:10869-10877, 2014), the targeted fertilization of free-oil phases or NAPLs (Environ. Sci. Technol. 45:1074-1081, 2011), by modulating the deposition and tactic motility of microbial degraders in porous media (Environ. Sci. Technol. 46:6790-6797, 2012), and by root exudates (Soil Biol. Biochem. 57:830-840, 2013; Environ. Sci. Technol. 49:4498–4505, 2015). However, a negative influence on biodegradation of PAHs by humic acids (Environ. Pollut. 184:435-442, 2014) and biosurfactants (Environ. Pollut. 205:378-384, 2015) was found if they prevented cell attachment to the PAH-loaded PDMS sources. These influences of DOM on bioavailability are relevant not only for innovation efforts in bioremediation but they have also connections with the determination of bioavailability of organic chemicals in retrospective and prospective risk assessment and regulation (Environ. Sci. Technol. 49:10255-10264, 2015).

TH023

Investigation of motor oil biodegradation by different bacterial strains

M. Ilic, IChTM / Department of Chemistry; S. Bulatovic, M. Ljesevic, Faculty of Chemistry, University of Belgrade; T. Šolević Knudsen, Institute of Chemistry, Technology & Metallurgy, University of Belgrade / Centre of Chemistry; J. Milic, Institute of Chemistry, Technology & Metallurgy / Centre of Chemistry; J. Avdalovic, S. Miletic, G. Gojgić-Cvijović, Institute of Chemistry, Technology and Metallurgy, University of Belgrade / Department of Chemistry; M.M. Vrvić, Faculty of Chemistry, University of Belgrade / Faculty of Chemistry

Large amount of motor oil is used in many branches of industry. The new generation of motor oils contains high percentages hydrocarbons (C16-C36), more than 75% cycloalkane and polycyclic aromatic hydrocarbons (PAH). However, used motor oils contain a higher percentage of aliphatic and aromatic hydrocarbons, nitrogen and sulfur compounds, and metals (Mg, Ca, Zn, Pb, etc.). In addition to these compounds, the presence of PAHs (naphthalene, benzo [a] pyrene and anthracene) is also expected. Therefore these oils represent a great danger to the environment, because all these compounds are known as mutagenic and carcinogenic [1, 2]. Globally, biodegradation is a common choice for remediation, because the pollutants become substrates for the growth of microorganisms [3]. The aim of this experiment was to investigate the biodegradation of motor oil by bacteria *Stenotrophomonas sp*. (NR 1), *Rhodococcus sp*. (UG 10) and *Bacillus sp*. (F 231) isolated from activated sludge ofindustrial wastewater treatment plant. The process of biodegradation of motor oil was monitored for 45 days. Each 15 days the process was stopped, the hydrocarbons were extracted, and the samples were analyzed by gas chromatography. Comparison of motor oil concentration in the samples and in the abiotic controls provided insight into the biodegradation activity of bacteria. The results showed a reduction in concentration of motor oil comparing to the beginning of the experiment (300 ppm). The growth of bacteria confirmed that the motor oil was the only source of carbon. The reduction of motor oil concentration was correlated with the number of bacterial cells. Based on these results, it was concluded that the biodegradation activity was highest in *Bacillus sp.* (F 231). After 45 days this bacterial strain degraded 95.4% of motor oil. Under the same conditions two other bacterial strains showed lower biodegradation activity: 84.9% by *Stenotrophomonas sp.* (NR 1), and 76.6% by *Rhodococcus sp.* (UG 10). Keywords: biodegradation, motor oil, bacterial stains References: [1] Bhat, M.M., Shankar, S., Shikha, Yunus, M., Shukla, R.N., *Adv. Appl. Sci. Res.* **2** (2011) 321-326. TH024

Bacterial community structure and biogeochemical activity in an aquifer contaminated with pesticides

a. Mauffret, BRGM / Environmental biogeochemistry and water quality; N. Baran, M. Charron, C. Joulian, BRGM

Our objective was to assess the effect of cocktails of pesticides on groundwater microbial abundance, community structure and their nitrate reducing activity. We used two complimentary approaches: a 2-year *in situ* monitoring at the Ariege alluvial plain (France) and microcosms with groundwater with contrasted contamination history spiked with selected herbicides having a high occurrence in this aquifer, atrazine (ATZ), desethylated atrazine (DEA) and ATZ+DEA. Abundance of the universal marker (16S rRNA) and of nitrate-reducing bacteria (*nar*G and *nap*A) was assessed by qPCR. Presence of the ammonium oxidizer was monitored by the *amoA* gene by PCR. Biodiversity was assessed using a fingerprinting technic (CE-SSCP). Pesticides in water were analyzed by LC-MS/MS. In microcosms, biodiversity was higher in historically contaminated water than in pristine-like one and remained higher under laboratory incubations. Biodiversity was significantly affected by both the chemical concentration and the incubation duration (not the chemical type) in the pritine-like water while in historically contaminated water, it was affected by the incubation duration only (not the chemical type or concentration), suggesting a community tolerance to the pesticides induced by chronic exposure. Biomass and denitrification gene abundance was in most cases higher at 10 μg/L than at 1 μg/L or in control, especially at 30-d incubation in both water types. During the two-year *in situ* monitoring, tendencies between chemical and microbial criteria were similar to the microcosm outcomes however they did not result in significant relationships. More specifically, it was not observed a significant relationship between nitrate concentration and microbial biomass and abundance of denitrifying genes (*narG* and *napA*). Microbial end points based on molecular indicators should be proposed to complete the biodiversity objective under the European water directive framework with the microbial compartment.

TH025

Analysis of the microbial community of the river Tiber in different contamination points along its course

A. Barra Caracciolo, National Research Council of Italy / Water Research Institute; P. Grenni, National Research Council of Italy (CNR) / Water Research Institute; S.M. Ludovica, National Research Council / Water Research Institute; D. Martina, Natonal Research Council / Water Research Institute; N. Ademollo, National Research Council of Italy / Water Research Institute; L. Patrolecco, Water Research Institute   Italian National Research Council; V. Ferrero, LGC; R. Loos, European Commission Joint Research Centre / Institute for Environment and Sustainability; S. Tavazzi, European Commission   Joint Research Centre / Institute for Environment and Sustainability IES; D. Mastroianni, F. Falconi, National Research Council / National Water Research Institute; t. lettieri, European. Commission - Joint Research Centre / Institute for Environment and Sustainability IES

One of the major issues in freshwater quality assessment is finding a link between the chemical and ecological status of a water system. Filling this gap is a new challenge for finding new biological indicators, by integrating multiple stressors, to describe/assess water quality thoroughly. In this context, the main aim of the MicroCokit FP7-PEOPLE-2012-IAPP Project is to identify microbial community based indicators for monitoring and evaluating different types of anthropogenic and environmental pressures. The case study is the river Tiber in which four different sampling sites along its course have been chosen and sampled in Autumn and Spring for 2 consecutive years. Except the pristine river source, the other three selected sites were differently exposed to anthropogenic pressures: Agricultural, Industrial and Anthropogenic one, respectively. Chemical analysis (inorganic elements, DOC, PAHs, organochlorine, triazine, chloroacetamide pesticides, perfluorinated compounds, pharmaceuticals, etc.) have been performed, together with the phylogenetic analysis of the bacterial community by Fluorescence In Situ Hybridization (FISH). Overall results of four sampling campaigns show how the changes in the microbial community structure reflect both natural environmental variations such as river course and seasonality, and the different sources of contamination.

TH026

Microbial turnover of PAH: analysis of degradation and dissolution kinetics and simulation of remediation options

A. Rein, Technische Universität München / Chair of Hydrogeology; I.K. Adam, A. Miltner, K. Brumme, M. Kästner, Helmholtz centre for environmental research - UFZ / Department of Environmental Biotechnology; S. Trapp, Technical University of Denmark / DTU Environment

Polycyclic aromatic hydrocarbons (PAH) are hydrophobic compounds exhibiting high toxicity and carcinogenicity. Originating from tar, coking and incomplete burning processes, PAH have contaminated many industrial areas and most urban soils. Feasible strategies for minimizing related adverse effects include the utilization of microbial degradation processes, where hardly soluble compounds like PAH pose a particular challenge. For the prospective assessment of the turnover of PAH there is a research gap since only very limited kinetic data for different groups of PAH degrader bacteria are available. In particular for Mycobacteria the knowledge is limited due to the complex cell cycle with formation of cell clusters and aggregates with PAH. From experiments and inverse modelling, growth and affinity parameters have been determined and compared for well described phenanthrene and pyrene degrading Mycobacteria on both substrates. The PAH were present as microcrystals in suspension. We refined a recently developed numerical model for desorption and metabolism, taking simultaneously into consideration chemical activity, sorption and dissolution processes, metabolism and growth as well as cell maintenance and decay in non-steady-state. This model was applied to prospectively describe PAH turnover dynamics for various treatment options to remediate contaminated soils. The investigated Mycobacterium species were not superior in PHE degradation to strains investigated earlier with this method. The amount of PAH ultimately degraded rather depended on the ad/desorption rates, and hereby on the substrate flux to the microbes, than on the Monod and Michaelis-Menten parameters of the strains. Predictive simulations revealed that bioaugmentation would only have a small and short-term effect on biodegradation. The addition of adsorbing soil amendments would shift the remaining PAH to the adsorbed/sequestered pool leading to a decrease in toxicity (lower mobility and bioavailability), but also to a lower diffusive flux to microbial cells and thus to declining activity of the PAH degrading microbes. Mobilization of PAH by adding solvents or surfactants would foster microbial activity, but might also increase toxicity. As the most promising strategy, stimulating cometabolism (e.g. by adding compost) could maintain microbial mass and activity at a high level leading to a steady decline of PAH in all pools. The model can thus be a valuable tool for assessing remediation options.

TH027

enviPath - The environmental contaminant biotransformation pathway resource

J. Wicker, University of Mainz; M. Guetlein, Johannes Gutenberg University Mainz; E. Schmid, ETH Zurich; D. Latino, Eawag Swiss Federal Institute of Aquatic Science and Technology; S. Kramer, Johannes Gutenberg University Mainz; K. Fenner, ETH Zürich/Eawag

The University of Minnesota Biocatalysis/Biodegradation Database and Pathway Prediction System (UMBBD/PPS) have been a unique resource covering microbial biotransformation pathways of primarily xenobiotic chemicals for over 15 years. This poster will introduce the successor system, enviPath (The Environmental Contaminant Biotransformation Pathway Resource), which is a complete redesign and reimplementation of UM-BBD/ PPS. enviPath uses the database from the UM-BBD/ PPS as a basis, extends the use of this database, and allows users to include their own biotransformation pathway data to support multiple use cases. As one new use case, we will present the package "DAR soil", which contains pathway information from soil degradation studies. This information has been extracted from pesticide registration dossiers (draft assessment reports, DAR) made publically available through the European Food Safety Authority. The package also contains information on different experimental conditions, which are stored as "scenarios". Compounds in the pathway are associated with a given scenario if they have been observed under the specific experimental conditions. If available, a biotransformation half-life (DT50) value is associated with a given compound in the pathway and a specific scenario. Much like the UM-PPS system, enviPath further provides different models to predict likely biotransformation pathways based on biotransformation rules. It supports relative reasoning for the refinement of predictions and allows its extensions in terms of previously published, but not implemented machine learning models. User access is simplified by providing a REST API that simplifies the inclusion of enviPath into existing workflows. An RDF database is used to enable simple integration with other databases. enviPath is publicly available at https://envipath.org with free and open access to its core data.

TH028

Evaluating and validating a Quantitative Structure Biodegradation Relationship (QSBR) model with experimentally determined biodegradation rates

k. acharya, Newcastle University / Environmental Engineering; M. Barycki, University of Gdansk / Department of Chemistry; J. Dolfing, P. Meynet, Newcastle University / Civil and Environmental Engineering; W. Mrozik, Newcastle University / School of Civil Engieenering   Geoscience; D. Werner, Newcastle University / Civil Eng and Geosciences; T. Puzyn, University of

Gdansk / Department of Chemistry; R. Davenport, Newcastle University / School of Civil Engineering and Geosciences
Biodegradation is a principal fate process of organic chemicals in the environment that affects regulatory persistence assessments and the design and operation of effective biological wastewater treatment systems to protect the aqueous environment. The rate of biodegradation is particularly difficult to predict as it is influenced by many different factors. These include inherent ones, such as the chemical structure, and external ones, such as the probability of encountering a bacterium able to degrade the chemical in a given environmental compartment. The systematic investigation of these factors has received little attention. In this study, we have so far developed a set of quantitative structure biodegradation relationships (QSBRs) for diverse set of aromatic micro-pollutants, which relate biodegradation rates (estimated from EPISuite) to different molecular descriptors. Such rates are derived from several biodegradation databases, which often lack accurate quantitative information for reliable determination of the rates. To experimentally validate one of the models, we have therefore selected several representative chemicals to perform biodegradation experiments using bacteria with known degradation pathways. A complete mass balance of each chemical was conducted by measuring the chemical concentration, microbial growth and carbon dioxide during the experiment. Finally, the biodegradation rate of the selected chemicals was estimated using these data and compared against the molecular descriptors from our previously developed model to test the robustness of its predictions.

Mercury Biogeochemistry and Policy (P)

TH029

Relationship between Hg species in seawater and microbial communities in the Middle Adriatic Sea

I. Zivkovic, M. Horvat, Jozef Stefan Institute; M. Solic, Institute of Oceanography and Fisheries; J. Kotnik, V. Fajon, Jozef Stefan Institute
Chemical and biologically mediated reactions can transform mercury species in the water column. These reactions can facilitate mercury's entrance into the marine food web in which it bioaccumulates in the form of methylmercury (MeHg). Factors that promote nutrients intake probably also facilitate MeHg accumulation in the microbial biomass. Singled-celled organisms represent the major components of marine community, especially in oligotrophic areas such is the Adriatic Sea. In these conditions, small organisms are better competitors for inorganic and organic nutrients because of lower energetic costs, rapid metabolism and small size. Microorganisms might represent a critical Hg bioaccumulation step in the entire marine food web. In order to establish relationship between Hg and microbial species, we performed sampling campaign in the Middle Adriatic Sea. Samplings were conducted from March 2014 to June 2015 during oceanographic cruises aboard the Croatian research vessel Bios Dva. Our research was constrained to transect from the Bay of Kaštela to the island of Vis. We collected non-filtered water samples for determination of total mercury (THg), dissolved gaseous mercury (DGM), methylmercury (MeHg) and picoeukaryotes in Adriatic coastal and open waters. Near the island of Vis, THg concentrations are the lowest and range from 0.14-1.10 ng/L. Mercury contamination from chlor-alkali industrial waters in the Bay of Kaštela is seen through the highest THg concentrations (0.92-5.58 ng/L). DGM is always higher in the contaminated areas (31.8-351 pg/L) than in the pristine environment (22.1-245 pg/L). MeHg concentrations vary, but range from 1.07-34.3 pg/L for all stations. The highest MeHg values are usually found in the Bay of Kaštela. Number of picoeukaryotes is the highest the Bay of Kaštela (0.44×10^6-31.8×10^6/L) which is affected by effluents from the surrounding cities, while the lowest number (0.63×10^6-19.9×10^6/L) is found in the pristine environment of the island of Vis.

TH030

China's current mercury policies and their implications for the overall success of Minamata Convention

T. Larssen, Y. Lin, Norwegian Institute for Water Research NIVA
China is currently the biggest emitter of atmospheric mercury, accounting for 1/3 to 2/5 of global emission depending on the study methods. Asia especially China is the net exporter of mercury through atmospheric transport. The projections of atmospheric emission of mercury also shows China's significant role in global mercury emission in 2050. What policies China currently has to reduce the impacts of mercury contamination, and whether there are major gaps in the current policies are key questions for the overall success of Minamata Convention. Here, we reviewed the current Chinese policies related to mercury under the context of Minamata Convention. Based on the information, we assessed compliance situation for the different convention obligations, and identified important policy gaps. China has been aware of the development of international efforts on a legal binding treaty to reduce global mercury pollution and been actively participating in all rounds of intergovernmental negotiations. Currently China has already had a set of policies to reduce mercury contamination and consumption which address most of articles of Minamata Convention. With the increasing awareness, China has a strong policy emphasis on source control, including reducing mercury emission (Article 8), mercury-added products (Article 4) and mercury catalyst used in vinyl chloride monomer industry (Article 5). However fewer efforts have been made for the trade and supply (Article 3), interim storage (Article 10) and waste handling (Article 11), the content of these articles are too a large extent addressed by the current general policy and regulations for all types of waste and chemical management. Though China has already a comprehensive set of policies and regulations which may serve as basis for the implementation of Minamata Convention, there are some important issues which are not addressed sufficiently by the existing policies, including the capacity problem for emission measurement and monitoring, phase-off of mercury containing devices, no retrospective mercury (chemical) management system and lack of information on mercury release to water and soil.

TH031

Use of the RISK21 Matrix: Impact of Mercury Species Exposure to Fish and Seafood on Human Health Risk in Taiwan

Y. Shu-Han, National Health Research Institute / National Institute of Environmental Health Sciences; W. Chan, P. Lin, National Health Research Institutes / National Institute of Environmental Health Sciences
Methylmercury (MeHg) is a highly toxic mercury species and associated \nwith variety of adverse health effects in humans and animals. Fishery resource \nis an important industry in Taiwan. Moreover, fish and seafood are the main \ndietary sources that provide protein, nutrients and omega 3 fatty acids. However, \nexposure to MeHg via fish/seafood consumption is a potential human health \nrisk factor worldwide. Therefore, it is important to be able to prioritize fish and \nseafood products on decisions making of fishery management for government \nand to quantify the MeHg exposure to fish and seafood for health risk \nassessment. \nThe purposes of this study were threefolds: (i) to estimate the intake of \nMeHg and total mercury (THg) via fishs and seafoods in all age groups, (ii) to \nprioritize which fishs and seafoods should be considered for human health risk, \nand (iii) to assess the culinary treatments of fish and seafood for assessing the \nhealth risk of MeHg and THg. \nThe exposure data were collected to assess different age groups intake \nTHg/MeHg concentrations from published papers, research papers, and the \nnational food consumption database in Taiwan. The toxicity information of \nMeHg and THg was based on toxicity data of contaminants from United States \nEnvironmental Protection Agency Integrated Risk Information System on-line \ndatabase. The RISK21 risk visualization matrix was used to assess estimates \nof exposure and toxicity together that can provide a clear view of human safety \nand risk. Finally, a probabilistic risk assessment framework was used to predict \nMeHg intake risk on culinary treatments of fish and seafood. \nThe preliminary results indicated that (i) consumption of saltwater fish has \nmore safety concern than that of freshwater fish and (ii) children and elderly \ngroups should be further evaluation than adolescent and adult groups by using \nthe estimates of toxicity based on available data. We suggest that the RISK21 \nmatrix serves as a useful tool to communicate with stakeholders and \ngovernment. KEYWORDS: Methylmercury, Fish, Risk Assessment, RISK21 Matrix

TH032

Dissolved organic matter controls mercury photoreactions in freshwater lakes

S. Klapstein, Acadia University / Earth Environmental Science; S. Ziegler, Memorial University of Newfoundland / Earth Science; D. Fischer, Bayer CropScience LP / RD Environmental Safety; N.J. O\'Driscoll, Acadia University / Department of Earth and Enviromental Science
Methylmercury (MeHg) contamination through bioaccumulation and biomagnification is an issue in many remote ecosystems far from direct pollution sources. Quantifying why and how some ecosystems are more sensitive to contamination following atmospheric mercury deposition is key to mercury fate modeling. Once bacterially methylated and transported into the water column of lakes photodemethylation of MeHg is thought to be one of the main processes in which MeHg can be converted into a less biologically toxic form. While previous studies highlight the importance of photodemethylation to mercury budgets, few have examined the magnitude and variability of photodemethylation rates as a function of associated dissolved organic matter (DOM). DOM absorbs specific wavelengths of solar radiation and therefore MeHg that is bound to these compounds containing photoreactive functional groups may be more readily degraded than unbound MeHg. Alternatively, DOM may absorb much of solar radiation in the top few centimeters of the water column and inhibit photodemethylation with depth. A temporal comparison study between summer and fall was conducted using lake water collected from 6 lakes in Kejimkujik National Park, Nova Scotia, Canada. Sample lakes were chosen based on a known range of DOM concentration. Lake waters were filtered to 0.45 µm and placed in closed polytetrafluoroethylene (PTFE) bottles with >50% headspace, spiked with 3 ng/L MeHgOH, and exposed to 0, 1, 2, 3, 5, and 7 days of natural solar radiation in each experimental season. Solar radiation and water temperature were measured every 5 minutes for the duration of the experiment. Ultraviolet (UV)-visible absorbance scans (200-800 nm), DOM concentrations, total mercury concentrations, and MeHg concentrations were measured for each time point. Dark controls had no significant reduction in MeHg concentration (all p's>0.1) supporting the hypothesis that all MeHg losses in the clear bottles were due to photodemethylation. Photodemethylation rates between lakes were compared

using ANCOVAs and showed that lakes with higher DOM concentrations had significantly lower rates of photodemethylation than lakes with lower DOM concentration ($p < 0.001$). Climate change in temperate and boreal regions of Atlantic Canada is projected to increase rainfall amounts and occurrences and thus lead to browning of freshwaters and further inhibition to the photodemethylation pathway of MeHg reduction.

TH033

Mercury concentration in PM10 collected in the Metropolitan Area of Mexico City

O. Morton-Bermea, Universidad Nacional Autonoma de Mexico; E. Hernández-Álvarez, S.L. Ordoñez-Godínez, G. Salinas-Larios, Instituto de Geofísica Universidad Nacional Autónoma de México; A. Retama, Secretaria de Medio Ambiente del Gobierno del Distrito Federal

The anthropogenic emissions are leading to a general increase of mercury in the environmnet. Urban areas are particularly affected since they are exposed to wide diversity of sources, Chemical information obtained from monitoring programs is relevant to identify emission sources. In order to evaluate the contribution of Hg to environmental pollution of the Metropolitan Area of Mexico City, airborne particles ≤ 10 µm (PM_{10}) were collected at four different sites in the urban. Samples collected during 2004 to 2014 were selected to be analyzed. Mercury determinations were carried out by inductively coupled mass spectrometry (ICP-MS). Average Hg concentration in the analyzed particulate matter are 77.0 pg m^{-3} in the. No spatial trend is evident.

TH034

Divalent metal resistance of mercury resistant bacterial isolates and their potential for mercury bioremediation

K. Mahbub, K. Krishnan, University of Newcastle / Global Center for Environmental Remediation; M. Mallavarapu, University of South Australia / Global Center for Environmental Remediation; R. Naidu, University of Newcastle / Global Center for Environmental Remediation

Three mercury resistant bacterial isolates were tested for the presence of mercury resistant genes in their chromosomal DNA, and evaluated for their toxic response to divalent metal ions specifically cadmium (Cd), lead (Pb), zinc (Zn) and copper (Cu) in liquid media. The genes involved in mercury resistance namely *merT*, *merP*, *merR* and *CYC* were detected, amplified and sequenced from the bacterial isolates. The deduced amino acid sequences of mercury resistant genes demonstrated homology with genes from a diverse microbial group. Isolate *Sphingobium* SA2 and *Sphingopyxis* SE2 showed resistance to all tested divalent metals to varying degrees while grown in individual metal supplemented low phosphate media. Whereas isolate *Pseudoxanthomonas* SE1 did not show tolerance to the divalent metals. For isolate *Sphingobium* SA2, the 72 h EC_{50} values of Cd, Pb, Zn and Cu were 13, 26, 62 and 3 mg/L respectively; whereas for isolate *Sphingopyxis* SE2 these values were 3, 27, 3 and 5 respectively. Since mercury contaminated soil and water are likely to contain other divalent heavy metals, the multi-metal resistance of mercury resistant bacterial isolates SA2 and SE2 show great potential for their application as bio-agents for the remediation of mercury contaminated soil and water.

Mercury bioavailability and toxicity to green microalga

R. Beauvais-Flueck, Institute Forel Earth and Environmental Sciences; V. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel; C. Cosio, Geneva University / Institute Forel Earth and Environmental Sciences

Bioavailability is a key concept allowing to link the changes in contaminant concentrations and speciation with the biological responses. It is also central for the understanding of Hg incorporation in the aquatic food web and possible implications for the environmental health. Nonetheless, in the specific case for Hg exposure the capabilities of the bioavailability to green microalgae, representing the base of the aquatic food chain in aquatic systems is not fully understood. The present study, therefore, explores the links between the chemical speciation, bioavailability and short-term induced effects of inorganic Hg (IHg) and methyl Hg (MeHg) to microalga *Chlamydomonas reinhardtii* under environmentally relevant exposure concentrations. The bioavailability was characterized by intracellular Hg contents at 10^{-10}, 10^{-9} and 10^{-7} M IHg or 5×10^{-11}, 5×10^{-10}, 5×10^{-9} and 5×10^{-8} M MeHg. It was further linked to the following biological endpoints: (i) the oxidative stress (ii) the photosynthesis efficiency and the differential gene expression. Chemical speciation in the exposure medium was also calculated and linked to the bioavailability. Obtained results demonstrated an increase of the intracellular Hg and MeHg contents with the concentration in the exposure medium. The number of up or down regulated transcripts increased with increasing intracellular Hg contents of both IHg and MeHg. At the similar intracellular content, the number of the affected transcripts was higher for MeHg than IHg at similar bioaccumulation supporting that MeHg has a stronger impact on algae than IHg. Furthermore, exposure to MeHg increased photosynthesis efficiency and up-regulated of many genes involved in this biological pathway for all studied concentrations, while IHg induced similar effects but only at highest exposure concentration. MeHg induced increase of the percentage of the cells experiencing oxidative stress, while no oxidative stress was detected for IHg exposure. Overall the present results demonstrated the stronger response of algae upon MeHg exposure as compared to IHg for comparable intracellular concentrations. The outcomes of this basic research contribute to the development of early warning biomarkers in support to biomonitoring efforts of mercury monitoring programs in aquatic systems.

TH036

Dietary transfer of Hg from Elodea nuttallii to Gammarus fossarum

R. Beauvais-Flueck, Institute Forel Earth and Environmental Sciences; a. chaumot, Irstea / UR MALY Laboratoire Ecotoxicologie; F. Gimbert, University of Franche-Comte / UMR ChronoEnvironnement; O. Geffard, Irstea / UR MALY Laboratoire Ecotoxicologie; C. Cosio, Geneva University / Institute Forel Earth and Environmental Sciences

In the aquatic environment, the organic form of Hg, methyl-Hg (MMHg) and inorganic Hg (IHg) are both toxic, but MMHg has been shown to biomagnify through food chain while IHg does not. Nonetheless, the precise factors controlling the transfer of Hg from primary producers to heterotroph consumers remains poorly understood. Macrophytes are key organism of shallow aquatic environment in which MMHg is produced, and have been identified as having a role in Hg transfer to food webs. The objective of this study was therefore to assess how the compartmentation of IHg and MMHg in a representative macrophyte, *Elodea nuttallii*, affects their bioaccumulation through dietary transfer in *Gammarus fossarum* chosen as surrogate species for aquatic herbivores and decomposers. Bioaccumulation of Hg in *E. nuttallii* was higher for cell wall than intracellular in line with previous studies showing an important role of binding of Hg in cell wall in *E. nuttallii*. Our data suggest no substantial demethylation or methylation during bioaccumulation in *E. nuttallii in planta* or in water. THg and MMHg concentrations increased in Gammarids in correlation with concentration found in *E. nuttallii*. MMHg was more transferable than IHg, based on THg, but a significant part was demethylated during the feeding, while no methylation was observed in the IHg exposure. Cell wall results in higher concentrations than intracellular, suggesting that Hg in cell wall in form of MMHg and IHg was significantly assimilated by Gammarids. Significant uptake fluxes were estimated by the first-order model: uptake fluxes in Gammarids were higher for cell wall than intracellular, while similar uptake rates were observed for IHg and MMHg. In conclusion, *G. fossarum* is able to feed on *E. nuttallii* and accumulates Hg from intracellular and cell wall compartments. In line with literature, when looking at THg, consumption of MMHg-exposed plants leads to slightly higher accumulation of Hg than IHg-exposed plants, but we observed a significant demethylation of MMHg in Gammarids *vs* plants. Opposite to literature, we did not observed a significant biomagnification of MMHg. In sum, although the subcellular metal distribution is determinant for many consumers that are unable to assimilate the insoluble fraction of cell walls, the digestive strategies to handle food of the consumer is also important. Differences in primary producers and consumers species composition may significantly influence the fate of Hg in food webs.

TH037

Bird colonies as secondary sources of Hg in Antarctic ecosystems: the use of vegetation and soil as indicators

C. Zecchin Cipro, Université de La Rochelle / LabQOM; R.C. Montone, Instituto Oceanografico - Universidade de Sao Paulo / Departamento e Oceanografia Fisica Quimica e Geologica; P. Bustamante, LIENSs CNRS & Université de la Rochelle UMR 7266 / LIENSs

"Global distillation" is classically pointed as the biggest responsible by contaminants input in Polar ecosystems. Besides that, mercury (Hg) presents natural sources as well, in a lesser scale. Nevertheless, the concentration of Hg along the life of organisms (bioaccumulation), and also along the trophic webs (biomagnification), combined with the fact that individuals gather in large numbers and excrete on land are particularly noticeable for seabirds during the reproductive season. Only a few studies proposed such colonies as an important secondary contaminants source for terrestrial or aquatic Polar ecosystems. In a previous study using vegetation as indicator we showed that seabird colonies constitute non-negligible sources of organic contaminants. In this context, the present work evaluates the influence of seabird colonies as secondary sources of Hg using both soil and vegetation as indicators in maritime Antarctic ecosystems, considering geographical variation, distance to the colonies and the use of different bird species with different feeding ecology strategies. Samples of lichen (n=55), mosses (n=58) and soils (n=37), were collected in 13 locations within the South Shetlands Archipelago in the austral summers of 2013-14 and 2014-15 and divided in two types: "colony" (within the colony itself for soil and bordering it for vegetation) and "control" (at least 50m away from the respectively closest colony). Preliminary results (dry weight) for lichens range from 0.077 to 0.705 $\mu g.g^{-1}$, with control samples generally less contaminated than colony ones. There were however exceptions i.e., the locations close to research stations, probably due to fossil fuel burning, and the locations in Deception Island, subject to volcanic activity. Mosses, in turn, range from 0.018 to 0.389 $\mu g.g^{-1}$. Contrary to lichens, they are more water-dependent and are not only subject to dry deposition, but also to contaminants in the water-phase and normally occur in less exposed and often ice-covered areas (except during the summer), remaining less exposed to evaporated/resuspended/lixiviated Hg from colonies. The concentration distribution was roughly the same as for lichens. For soils, results range from 0.005 to 0.302 $\mu g.g^{-1}$, with no exceptions: control samples were always less contaminated than the colony ones. These patterns may indicate colonies as possible Hg sources. Further data treatment will allow to estimate and quantify the influence of those variables.

TH038

Influence of Avian Biovectors on Mercury Speciation in a Wetland

J. Kickbush, Acadia University / Biology; M. Mallory, J. Rand, J. Murimboh, Acadia University; N.J. O\'Driscoll, Acadia University / Department of Earth and Enviromental Science

Mercury is a persistent and bioaccumulative chemical that is present in many remote environments due to its ability to be transported long distances in the atmosphere, and to be deposited far from the original source (Sunderland and Chmura 2000). Wetland ecosystems are important "hot spots" for mercury in eastern Canada, providing anoxic environmental conditions that promote the bacterial methylation of mercury. Methyl mercury is the most biologically available form of mercury and the form which biomagnifies in food webs (Gochfeld 2003). Seabird guano is a well-documented biovector for metals – including mercury – and nutrients, which may indirectly affect metal speciation (Choy et al. 2010). The site for this study, Big Meadow Bog (Brier Island, Nova Scotia, Canada) has a history of ditching in the 1950s, which changed hydrology significantly, resulting in colonization by 3000 pairs of herring gulls (*Larus argentatus*) in the 1980s. To quantify changes in mercury mobilization and speciation in response to this biovector, groundwater samples were collected from this site as well as a reference bog with similar geological and hydrological characteristics. The filtered samples were analyzed for total mercury, methyl mercury, and water chemistry (pH, conductivity, anions, cations, and dissolved organic and inorganic carbon). Preliminary results show significantly higher nutrients (nitrate, phosphate, and sulfate), total mercury, and methyl mercury concentration when compared to the reference bog that is minimally impacted by avian biovectors. This elevated availability of methyl mercury could potentially pose a threat to the local ecosystem and wildlife population due to methyl mercury's toxicity to living organisms (Akearok et al. 2010, Singh et al. 2011).

TH039

Toxicity Reference Values for Methylmercury Effects on Birds: Critical Review and Analysis

P.C. Fuchsman, M.H. Henning, M.J. Bock, V.S. Magar, Ramboll Environ

Effects of mercury on birds have been studied extensively and with increasing frequency in recent years. Some highly exposed populations have exhibited adverse effects related to environmental methylmercury exposures while other species are relatively tolerant. We conducted a systematic review of methylmercury effects on bird reproduction, evaluating laboratory and field studies in which observed effects could be attributed primarily to mercury. Our review focused on exposures via diet and maternal transfer in which observed effects (or lack thereof) could be associated with mercury concentrations in diet, eggs, or adult blood. While dose-response data sets were limited to a few species, no observed effect levels, lowest observed effect levels, and/or effect thresholds (e.g., effects of approximately 20%) could be identified for more than 20 species. From this data set, we identified ranges of toxicity reference values (TRVs) suitable for risk assessment purposes. For mercury in avian blood, this represents the first broad compilation of relevant toxicity data. For dietary exposures, the current data support TRVs that are higher than older, commonly used TRVs. The older diet-based TRVs incorporated conservative assumptions and uncertainty factors that are no longer justifiable, although they were appropriate due to limited data at the time those TRVs were derived. The egg TRVs identified from this review are more similar to other previously derived TRVs but have been updated to incorporate new information from recent studies.

TH040

Mercury trend governed by fish population demography?

A. Ruus, NIVA / NIVA; D. Hjermann, Norwegian Institute for Water Research (NIVA); B. Beylich, N. Green, NIVA

Mercury (Hg) is a toxic element entering the biosphere from natural and anthropogenic sources. Mercury in Atlantic cod (*Gadus morhua*) is one of many things that are monitored through the Norwegian contribution to the Coordinated Environmental Monitoring Programme (CEMP) carried out by the Norwegian Institute for Water Research (NIVA) by contract from the Norwegian Environment Agency. CEMP is administered by the Oslo and Paris Commissions (OSPAR) in their effort to assess and remedy anthropogenic impact on the marine environment of the North East Atlantic. Time series for cod in the Inner Oslofjord (Norway) goes back to 1984. Annual median Hg-concentrations in cod from the Inner Oslofjord (Norway) showed both significant upward long-term (whole time series) and short-term (last 10 years) trends. However, the median length of the cod sampled also showed an upward trend. This is consistent with results of beach seine surveys (dating back to 1919) conducted in the Inner Oslofjord, showing that cod recruitment in the area has been low since the start of the 2000s. To investigate how length would impact the trend analysis, the Hg-concentrations in the cod fillet were normalized to two arbitrary lengths: 40 cm and 60 cm. No significant trend in Hg-concentrations could be detected for either 40 cm-normalized, or 60 cm-normalized cod the last 10 years. The results indicated that most of the upward trend in Hg-concentrations could be attributed to the catching of larger fish. The influence of other explanatory variables than length needs to be explored. It is not merely aquestion of why mercury is apparently increasing in cod, but also what are the reasons for the apparent change in the cod population demography. In this regard, sampling bias must also be considered.

TH041

The fate of mercury legacy in the contemporary environment; From old mines to brown trouts

S.V. Hansson, Laboratoire EcoLab, Ecologie Fonctionnelle et Environnement (UMR5245 CNRS-Université de Toulouse) / Ecolab Laboratoire décologie fonctionnelle et environnement; J. Sonke, Observatoire Midi-Pyrénées, CNRS-GET-University of Toulouse / GET; G. LeRoux, ECOLAB UMR CNRS UPS INPT / Ecolab Laboratoire décologie fonctionnelle et environnement

Due to their geological features mountain environments have often been exploited since the beginning of metallurgy and the French Pyrenees is no exception. Results on trace metal concentrations in the Ariège region, where extensive mining (Ag, Fe) occurred from the Antiquity to the 19th century, indicates that ≥600 tons of anthropogenic Pb is stored in organic soils on the Pyrenean northern slopes. Similar conclusions can be drawn for other mining legacy pollutants (Hg, Zn). The fate of these trace elements in relation to climate or abrupt environmental changes (e.g. flood, forestry) is poorly understood. Once released from surrounding organic soils the catchment can be highly enriched in the bioavailable fraction of these metals causing a bioaccumulation of e.g. MeHg in river biota. In combination with predicted rise in global atmospheric mercury deposition, the mercury legacy from old mines may pose a severe threat to the biota in these already sensitive high altitude areas. E.g. preliminary results show that levels of tot-Hg in brown trout (*Salmo trutta*) caught at our study sites surpasses litterature values by 10 times or more. Further to this, MIF and MDF Hg-isotope signatures shows clear relationship with the size of the fish and also with $\delta^{15}N$. By linking data from atmosphere – soil – peat – water – sediment – biota, and the transfer between these continuums, we are studying the fate of legacy pollutants (Pb, Ag, Bi, Sb, Hg, As and U) with a main focus of Hg, in three mountain catchments (Etangs de Bassies, Largentière and Bernadouze) all located in the French Pyrenees. Our study also includes biofilm, invertebrates, common minnow and brow trout representing various aspect of the biotic food chain. We aim to infer the potential risk these legacy pollutants pose on river biota (i.e. fish) and environment at large. To do so we combine traditional geochemical analysis (DMA, HR-ICP-MS) with stable isotopes (Pb and Hg, $\delta^{13}C$ & $\delta^{15}N$) and analysis of radiocarbon and radionuclides (^{210}Pb, ^{137}Cs, ^{241}Am and ^{7}Be) in order to investigate the origin of these elements. We also perform micronucleus analysis of the fish blood to test if any toxicological effects can already be seen. Our goal is to assess the potential harmful exposure these legacy pollutants in general and Hg in particular, may pose to the environment, to humans and to society at large.

TH042

Specific pathways and effects of dietary methylmercury and inorganic mercury in zebrafish (Danio rerio) determined by mercury speciation, genetic, histological and metallothionein responses.

s. gentes, UMR CNRS 5805 EPOC- Universite Bordeaux 1 / equipe ecotoxicologie Aquatique; R. Maury-Brachet, University of Bordeaux CNRS; c. feng, IPREM UMR CNRS Université de Pau et des Pays de lAdour; Z. Pedrero Zayas, E. Tessier, LCABIE-IPREM UMR 5254 CNRS-UPPA; A. Legeay, N. mesmer-dudons, M. Baudrimont, L. Maurice, UMR CNRS EPOC Universite Bordeaux; D. Amouroux, Laboratoire de Chimie Analytique Bio Inorganique et Environnement, UMR CNRS IPREM5254, University Pau.; P. Gonzalez, UMR CNRS EPOC Universite Bordeaux

A multidisciplinary approach is proposed here to compare toxicity mechanisms of methylmercury (MeHg) and inorganic mercury (iHg) in muscle, liver and brain from zebrafish (*Danio rerio*). Animals were dietary exposed to (1) 50 ng Hg. g^{-1}, 80% as MeHg; (2) diet enriched in MeHg 10000 ng Hg. g^{-1}, 95% as MeHg; (3) diet enriched in iHg 10000 ng Hg. g^{-1}, 99% as iHg, for two months. Hg species specific bioaccumulation pathways were highlighted, with a preferential bioaccumulation of MeHg in brain and iHg in liver. In the same way, differences in genetic pattern were observed for both Hg species, (an early genetic response (7 days) for both species in the three organs and a late genetic response (62 days) for iHg) and revealed a dissimilar metabolization of both Hg species. Among the 18 studied genes involved in key metabolic pathways of the cell, major genetic responses were observed in muscle. Electron microscopy revealed damage mainly due to MeHg in muscle and also in liver tissue. In brain, high MeHg and iHg concentrations induced metallothionein production. Finally, the importance of the fish origin in ecotoxicological studies, here the 7th descent of a zebrafish line, is discussed.

TH043

Determination of mercury and methylmercury concentrations at low levels in

rivers by passive sampling method and isotopic dilution GC-ICP-MS

A. Dabrin, Irstea Lyon-Villeurbanne / UR MALY; A. Magnier, M. Bretier, G. Grisot, Irstea Lyon-Villeurbanne; M. Coquery, Irstea Lyon-Villeurbanne / UR MALY

Diffusive gradient in thin film (DGT) samplers have been widely used as water quality monitoring tools to study cationic trace metals of the Water Framework Directive (WFD) (lead, cadmium, nickel). However, these samplers based on a polyacrylamide diffusive gel and a Chelex resin do not allow trapping methylmercury (MeHg) and inorganic mercury [Hg(II)] which is also a priority substance of the WFD. The most common DGTs developed for these two mercury species are based on a 3-mercaptopropyl functionalized silica gel (3M) resin, with a diffusive gel either in polyacrylamide or in agarose. However, previous studies focused on the application of such DGTs in relatively contaminated surface waters (total Hg in dissolved phase HgT_D >5 ng/L or MeHg in dissolved phase $MeHgT_D$ >0.25 ng/L). The aim of this study was to develop a home-made passive sampler combined with analysis by gas chromatography-inductively coupled plasma-mass spectrometry (GC-ICP-MS) to measure low levels of mercury species in surface waters. Consequently, our work first focused on the control of Hg contamination mainly via the control of blank DGT. Then, we developed an analytical method coupling isotopic dilution with GC-ICP-MS, which allowed the extraction, derivatization and quantification of the mass of Hg(II) and MeHg trapped by the home-made/3M DGT at environmental levels. For in-situ validation, triplicates of home-made samplers were deployed at three sites in a low contaminated river (HgT_D~0.5 ng/L), and we assessed time-weighted average concentrations (TWAC) for labile HgT_D and $MeHgT_D$. Our home-made/3M DGT resins contained significantly lower level of total Hg (Hg_{TOT}) (< LQ=0.03 ng) compared to commercial DGTs based on a spheron-thiol resin. These results clearly demonstrated that the initial mass of Hg in commercially available DGTs was masking Hg accumulation after deployment in a low contaminated river. Thus, in these environmental conditions, commercial DGTs are not well adapted. In contrast, our home-made/3M DGTs were suitable to assess TWAC of HgT_D in a low contaminated river. Then, the quantification of Hg(II) and MeHg trapped in the home-made/3M resin was achieved by isotopic dilution (ID), extraction with acidic thiourea solution and derivatization before measurement by GC-ICP-MS. This optimized, sensitive and reproducible method, combining passive sampling method (10 days deployment) and ID-GC-ICP-MS, allowed the measurement of low level of labile HgT_D and $MeHg_D$ (90-130 pg/L).

Mechanistic toxicology of engineered nanomaterials: state of the art and future perspectives (P)

TH044

Natural organic matter influences UV light induced toxicity of nano-sized titanium dioxide

S. Lüderwald, Universität Koblenz-Landau / Institute for Environmental Sciences; V. Dackermann, F. Seitz, University of Koblenz-Landau / Institute for Environmental Sciences; R. Rosenfeldt, Uniersity of Koblenz-Landau, Institute for Environmental Sciences / Institute for Environmental Sciences; T.C. Schell, R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment

The constantly growing application of nano-sized titanium dioxide ($nTiO_2$) leads to an increasing entry in aquatic ecosystems, e.g. through waste water effluents. Effects caused by $nTiO_2$ on aquatic life, however, vary substantially in their intensity, which is often attributed to particle characteristics. A well-known property of $nTiO_2$ is the formation of reactive oxygen species (ROS), inducing toxic effects at ambient UV light irradiations and low $nTiO_2$ concentrations. At the same time, natural organic matter (NOM) is suppressing the formation of ROS. Yet, only limited knowledge is available on the interaction of $nTiO_2$ with UV light and NOM. Therefore, this study assessed the toxicity of $nTiO_2$ (P25; ~90 nm; 0.00-128.00 mg/L) when interacting with increasing levels of UV light (0.00-5.20 W UVA/m²) and NOM (seaweed extract; 0.00-4.00 mg TOC/L) using acute toxicity tests with *Daphnia magna* as a model system. Results supported the hypothesis of a decreased effect of $nTiO_2$ in presence of NOM, whereas the presence of UV light increased the toxicity with an increasing intensity up to 280-fold (i.e., at 4.80-5.20 W UVA/m²) when compared to experiments in absence of UV. This pattern was attributed to amplifying ROS formation under higher UV light intensities. However, the $nTiO_2$ induced ROS formation was not inversely proportional to increasing NOM levels, i.e. lower concentrations (0.04-0.40 mg TOC/L) diminished, whereas a higher concentration (4.00 mg TOC/L) promoted the ROS quantity, irrespective of UV light intensity, which partly contradicts the results obtained by the *Daphnia* bioassays. Therefore, this study demonstrated that the combination of UV light and NOM had the potential to modify the direction and intensity of the effects caused by $nTiO_2$ relative to a consideration of impacts of UV light and NOM individually. Since the trigger for this joint effect of UV light and NOM on the toxicity of $nTiO_2$ remains unclear, further research on nanoparticle toxicity should be conducted with UV light and varying quantities and quality of NOM to uncover the governing mechanism influencing the formation of ROS.

TH045

Assessing aqueous phase silver nanomaterial (Ag NM) environmental fate; a flume based approach

C.C. Liddle, F.G. Lara, Heriot Watt University / School of Life Sciences; A. Cuthberson, Heriot Watt University / School of Built Environment; H. Haynes, Heriot Watt University / School of Energy Geoscience Infrastructure and Society; H. Johnston, Heriot Watt University / Life Sciences; T.F. Fernandes, Heriot-Watt University / School of Life Sciences

Flumes offer the ability to study Ag NM removal and persistence behaviour in controlled and potentially 'environmentally relevant' scenarios. Studying removal rates within flow systems may produce fate descriptors to translate processes into useful models which will help with exposure assessment in realistic conditions. The aim of this research was to develop flume based systems and methods to investigate aqueous phase Ag NM fate and behaviour within different aquatic conditions, and subsequently investigate the effects of flow, organic and inorganic matter, the presence of non-cohesive sediments and re-suspensions events on aqueous phase Ag NM removal/persistence and re-dispersion. Two Ag NM were studied within flume systems (flow velocity 0.12 m/s): Ag NM (PVP) (30-50nm), and analogous reference material NM300 (15±5nm), within two recirculating turbulent flow test systems containing 1.8 L and 55 L of soft water medium, respectively. Studies were carried out over a time course of up to 24 days. At the end of the experiment flow velocity was increased, when relevant, to entrain the bed sediment and create re-suspension events. Suwannee river humic acid (SRHA), Sigma humic acid and kaolinite clay were used as model organic and inorganic matter, and silica sand was also used as a model non cohesive sediment. Total aqueous phase Ag concentration (to assess removal), primary particle size of NM, aggregation state and zeta potential, and dissolution were investigated at specific time points in soft water medium, using a range of suitable methods. Results indicated NM300 removal rates and aggregation state within the aqueous system increased within turbulent flow relative to static systems, indicating turbulent flow significantly increased removal processes, which was attributed to increased sedimentation rates. The addition of kaolinite clay (20 mg/l) and humic acid (2 mg/l) did not significantly increase or stabilise Ag NM aqueous phase removal within flow conditions. However higher concentrations of humic acid (10 mg/l) resulted in longer term persistence of NM300 within the water column. The presence of non- cohesive sediments significantly increased removal rates of NM300. Ag NMs exhibited re-dispersion following re-suspension events. These results indicate that turbulent flow would be the dominating factor in modulating Ag NM removal in lotic water, when organic matter concentrations are low, and remobilisation of Ag NM needs futher consideration.

TH046

Influence of soil pH and plant specie in the leaching of Zn in two crops developed in soils spiked with ZnO-NPs, ZnO-bulk and ZnSO4 under greenhouse conditions.

D.G. Rodríguez, Universidad Politecnica de Madrid / Química y Tecnología de Alimentos; A. Obrador, Universidad Politecnica de Madrid; P. Almendros, Universidad Politecnica de Madrid / Química y Tecnología de Alimentos; M. Fernández, INIA / Environment; C. Garcia-Gomez, INIA / Dpto Environment

Nanotechnology is becoming increasingly important in the agricultural sector. Promising results and applications of nanoparticles (NPs) are already being developed in the areas of delivery of pesticides, fertilizers and genetic material for plant transformation. However, their use is not without risk (toxicity to ecosystems, phytotoxicity to crops and effects on both soil and water quality) which should be carefully evaluated. In recent years, rapid progress has been achieved in the study of phytotoxicity of NPs and accumulation in plants, but important issues still remain to be solved. Among them, the importance of the physicochemical soil characteristics for NPs toxicity and their potential to contaminate water compartments due to the transfer of contaminants from soil to water. The aims of this study were to evaluate the influence of soil pH and plant specie in the leaching of Zn, in two crops developed under greenhouse conditions, and in two soils spiked with ZnO-NPs, ZnO-bulk and $ZnSO_4$. A lysimeter experiment was carried out in two agricultural soils: an acidic soil (pH 5.4) and a calcareous soil (pH 8.3), using two plant species (*Solanum lycopersicum* L. and *Phaseolus vulgaris* L.) under greenhouse conditions. The upper part of the soil (3 kg of a total of 10 kg) were spiked with 3, 20 and 225 mg Zn kg^{-1} as ZnO-NP; 20 and 225 mg Zn kg^{-1} as ZnO-bulk; and 20, 100 and 225 mg Zn kg^{-1} as $ZnSO_4$. The soils were irrigated at slightly above field capacity moisture to obtain 6 portions (each of 400 mL) of leachate. The average Zn concentrations in the leachate were much higher in the acidic soil than in the calcareous soil. However, there were no differences with respect to the crop. According to LSD test ($P < 0.05$), in the acidic soil, total quantities of Zn in the leachate depended on the Zn treatment applied. There were no significant differences among total quantities of Zn leached from ZnO-bulk and ZnO-NPs treatments, for the same dose. However, these amounts were significantly higher for soils spiked with $ZnSO_4$ (except for the dose of 20 mg Zn kg^{-1}). The amount of leached Zn in treatments with doses less than 20 mg Zn kg^{-1} was comparable with that leached from the control. Regarding the amounts of total Zn leached for the same period in the calcareous soil, there were no significant differences among the treatment or crops with respect to total quantities of Zn in the leachate. This research was funded by the Spanish projects RTA2013-00091-C02-02 and RTA2013-00091-C02-01

TH047

Ecotoxicology of Sediment-associated Carbon Nanotubes.

n.h. ashri, T.F. Fernandes, Heriot-Watt University / School of Life Sciences; M. Hartl, Heriot-Watt University / Centre for Marine Biodiversity and Biotechnology School of Life Sciences

Carbon nanotubes (CNTs), single-walled (SWCNTs) and multi-walled (MWCNTs), are high aspect ratio nanostructures with a combination of properties making them useful in an increasing number of products and applications. Although CNTs occur in the environment as the result of natural combustion processes, significant environmental exposure to engineered CNTs would previously not have occurred and therefore they are considered xenobiotics. Investigations of CNT toxicity are complicated by factors such as the large variety and synthesis methods, as well as the lack of standardized testing procedures, but also their tendency to agglomerate in aquatic systems. Few *in vivo* studies have examined the behaviour of CNTs in marine systems and their bioavailability and toxicity to marine organisms. We have previously shown that SWCNTs show relatively low toxicity to marine mussels; the main concern was that SWCNTs influence the toxicity of other contaminants at otherwise benign concentrations. CNTs in the aquatic environment are expected to rapidly precipitate and become incorporated into sediments. The aim of the present study was to assess the behaviour of CNTs in sediments, their bioavailability to benthic species and their effect on the bioavailability and toxicity of other sediment-associated contaminants. Experiments showed that CNTs ($500\mu gL^{-1}$) could be recovered and confirmed using Raman spectroscopy (RS), albeit with very weak spectra; we are currently improving the technique. Ecotoxicological effects of sediment-associated SCNTs and MCNTs (dispersed in 0.02% SRNOM) were investigated by injecting them into seawater tanks (pH7.9-8; 20°C) containing light-coloured play pen sand washed playpen sand. CNTs were left to settle on to the sediment surface, after which cockles (*Creastoderma edule*) were introduced and left to bury and filter-feed the nephloid layer for 72hrs. Uptake of CNTs was confirmed using RS and TEM imaging. A suite of biomarkers of exposure were studied, including oxidative stress (SOD, CAT, TBARS, GSH, GPx) and associated genotoxicity. CNTs settled down very quickly after one hour and no changes in their behaviour were observed after 24 hr. Early genotoxicity data suggest that sediment-associated CNTs caused an increase in DNA strand breaks in *C. edule* at concentrations $>100\mu gL^{-1}$. Work is currently ongoing to extend the exposure concentration range down to more environmentally relevant levels and to test the causative oxidative stress hypothesis.

TH048

Investigating the effects of nanomaterials from waste water treatment plants; removal, release and subsequent impacts

A. Georgantzopoulou, A.L. Macken, NIVA Norwegian Institute for Water Research; K.V. Thomas, NIVA Norwegian Institute for Water Research / Product Metabolism

The majority of nanomaterials (NMs) used for commercial applications will enter the waste water treatment plant. In many countries the waste water effluent and sewage sludge are discharged in aquatic environments or applied in agricultural land, however, the transformation of the particles and the potential hazard they pose in these compartments are poorly understood. The main aim of the study is to understand the transformation of NMs during the waste water treatment processes and to evaluate the potential environmental hazard of the transformed `aged´ particles compared to the pristine ones. Initial investigations focus on the study of silver and titanium particles incorporating the use of iosotopically labelled particles as well as unlabelled, to better understand the behaviour and fate of these particles in complex media and biological systems. An integrative approach is taken using organisms of multiple trophic levels representing the aquatic and terrestrial environment. A biodynamic study is envisioned for the assessment of uptake, elimination, bioaccumulation and intracellular localization of the NMs both in the pristine form as well after their transformation during the waste water treatment processes. Moreover, *in vitro* cell culture models of high relevance for nanoparticle toxicity assessment representing the main sites of nanoparticle uptake and excretion such as the gills and liver have been developed and incorporated in order to identify possible modes of action.

TH049

Impact of silver and silver nanoparticles on the structure and functionality of microbial communities in sewage treatment plants

M. Matzke, Centre for Ecology & Hydrology (NERC) / Molecular Ecotoxicology; W. Tyne, NERC Centre for Ecology Hydrology; S. Faetsch; S. Stolte, Sustainable Chemistry; A. Oliver, L. Newbold, H. Gweon, D. Read, NERC Centre for Ecology Hydrology; D. Spurgeon, Centre for Ecology & Hydrology; R. Verweij, Department of Ecological Science VU University Amsterdam The Netherlands; C. Svendsen, CEH, Wallingford / Pollution and Ecotoxicology

Silver nanoparticles (AgNPs) are amongst the most commonly used nanoparticles in consumer products. Therefore they will inevitable end up in the environment mostly through the entry pathways of sewage sludge to soils (application to fields as a fertilizer) or effluent to freshwater systems. However, due to the antimicrobial properties of silver, the microbial communities in the sewage treatment plants might be affected resulting in a decrease of functional efficiency of the treatment processes. Standard tests to evaluate potential effects on microbial (sludge) communities (e.g. OECD 209) only considers short term effects with average contact times of only 3 hours. Silver is non-biodegradable and therefore has the potential to accumulate in the environment resulting in potential long-term effects on microbial communities. Aim of this study was to compare the effects of two concentrations (1 mg/L & 50 mg/L) of ionic silver ($AgNO_3$) and AgNPs on the community structure over a time period of 2 weeks. The selected silver nanoparticles were commercially available (Amepox, Poland), uncoated and paraffin stabilized with a primary particle size of 3-8 nm. The aqueous AgNP stock suspension (1000 mg/L) was characterized with DLS, NTA, TEM (size distribution and homogeneity) and AAS (for dissolved and total silver concentration). The diversity of the bacterial community and potential structural changes were analyzed with 16srRNA sequencing (dual index sequencing/MiSeq). Activated sludge was incubated for 2 weeks (aerated; fed every 3 days with meat extract) and samples for sequencing were taken at 4 time points (start (0), 2, 7 and 14 days) to track structural community changes. Silver concentrations were monitored in parallel for dissolved (post ultracentrifugation) and total silver concentrations by atomic adsorption spectroscopy (AAS).Analytical results showed in general a low total and dissolved silver concentration in the water phase staying relatively constant over the testing period suggesting that most of the silver was rapidly bound to the organic matrix at the beginning of the test. Microbial communities showed structural differences between the ionic and the silver nanoparticle treatments, but only after 7 days. The effects were most distinct for the 50 mg/L AgNO3 treatment (after 7 days). For all other treatments (1 mg/L $AgNO_3$/1& 50 mg/L AgNPs) significant effects were visible only after 14 days supporting the importance to analyse long-term effects.

TH050

The influence of soil properties on long-term effects of silver and silver nanoparticles on soil microbial communities

E. Lahive, Centre for Ecology & Hydrology (NERC); M. Matzke, Centre for Ecology & Hydrology (NERC) / Molecular Ecotoxicology; L. Newbold, A. Oliver, W. Tyne, H. Gweon, D. Read, A. Lawlor, NERC Centre for Ecology Hydrology; S. Lofts, Centre for Ecology & Hydrology / Shore Section; D. Spurgeon, Centre for Ecology & Hydrology; C. Svendsen, CEH, Wallingford / Pollution and Ecotoxicology

Metal and metal oxide nanoparticles (NPs) are currently the nano materials with the highest total production volume. Silver nanoparticles (AgNPs) have gained considerable attention due to their broad microbiocidal properties, which implies a specific hazard for exposed soil bacteria. Both chemical transformations of the NPs (e.g. dissolution) and the chemistry of the soil may modify the organism exposure and response in NP–dosed soils. Previous work has shown that soil type influences toxicity of ZnO NPs to microbial communities with soil pH playing a major role. In this study we investigated how soil properties influence the bioavailability and toxicity of silver (Ag) NPs and ionic silver to natural soil microbial communities. Soils were dosed with either 50nm diameter PVP-coated Ag NP or an ionic silver reference, silver nitrate ($AgNO_3$). Four soils were used for this study with a soil organic matter (SOM) content ranging from 1.8–16.7% and soil pore water pH from 4.5–8.3. Microbial communities were exposed to nominal soil concentrations ranging from 9 – 5500 mg Ag/kg. The diversity of the bacterial communities and potential structural changes were analyzed with 16s rRNA sequencing (dual index sequencing/MiSeq) at 4 time points; at test start, after 4 weeks, 8 weeks and 52 weeks. Soil pore waters were extracted from all soils at the beginning (t=0days) and after 8 weeks of the experiment, ultra-filtered (10kDa) and analysed for silver, pH and dissolved organic carbon. Results clearly showed an influence of silver and silver nanoparticles on soil microbial communities and clear differences in the community structure between the ionic and the AgNPs treated soils. At the beginning of the test effects of $AgNO_3$ were more distinct than for AgNPs, but with increasing exposure time these differences became less distinct, suggesting gradual dissolution of the AgNPs and a corresponding increasing impact of the released ions on the microbial community structure. Soil pH was identified as one of the key properties influencing bioavailability and toxicity of silver and AgNPs on the microbial communities. Our results also show that long-term effects (e.g. slow NP dissolution in soils over months) need to be considered for a realistic environmental hazard assessment of AgNPs.

Coating relevance in the nanoparticle toxic effect to Daphnia magna.

D. Hernandez-Moreno, INIA / Environment; J. Hernandez-Gonzalo, J. Navas, M. Fernandez-Cruz, INIA - National Institute for Agricultural and Food Research and Technology / Environment

Coating of nanoparticles (NPs) with a proper surface agent is usually required before their use in any application, to improve its functionality. This coating will determine the NP interaction with the environment as the physicochemical properties of the NPs can be modified due to this cover, leading to different effects in organisms. A major regulatory problem will be the high amount of assays that

should be conducted for all coating-NP combinations. In the framework of FP7 Project GUIDEnano we investigated the toxicity produced by different coatings on three metal NPs (synthetized from PlasmaChem GmbH, Germany) to try to establish relationships between coatings and toxicity. The acute effect of NPs, in terms of core composition (TiO_2, CeO_2 and Ag), was investigated on neonates of *Daphnia magna* after 48 h exposure following the OECD guidelines. The two first NPs were functionalized with three different coatings: citrate (TiO_2-CIT/CeO_2-CIT), polyethylene glycol (TiO_2-PEG/CeO_2-PEG), and dodecylphosphonic acid (TiO_2-DDPA/CeO_2-DDPA), moreover those NPs were tested also uncoated (TiO_2-UNC/CeO_2-UNC). AgNPs were coated with CIT, PEG and oleylamine (HPB). Both DDPA and HPB confer hydrophobic characteristics to the metal NPs, whereas CIT and PEG make NPs more hydrophilic. The highest immobilizing effect was found after exposure to AgNPs, showing the lowest IC_{50}. In those cases, assuming that Ag-CIT can behave as the uncoated NP, the toxic effect of the AgNPs increased by their functionalization with PEG and HPB. On the other hand, *D. magna* exposed to TiO_2-UNC and CeO_2-UNC presented higher toxicity than the same core coated with CIT, PEG or DDPA where no toxic effect was observed. Thus the coating conducted to a protective effect over the metallic core. The size of the NPs in the exposure medium could not explain this different behavior between metal-oxide and metal NPs. It is more likely that the coating interaction with the core lead to a different behavior of the NPs. From this study a specific pattern linked to the coating could be established depending on the core composition. The coatings of the metal-oxide nanoparticles eliminated completely the toxicity produced by the uncoated NPs. On the contrary, toxicity of the metal NPs was increased depending on the coating surrounding the AgNP.

TH052
The effects of a panel of nanomaterials on the freshwater microalga Pseudokirchneriella subcapitata
F.M. Alqahtani, Heriot-Watt University / School of Life Science; H. Johnston, Heriot Watt University / Life Sciences; V. Stone, Heriot-Watt University / School of Life Science; T.F. Fernandes, Heriot-Watt University / School of Life Sciences
The increased use of nanomaterials in a wide range of products is likely to lead to larger releases of nanomaterials into the environment. The aim of this study is to assess the effects of a panel of nanomaterials on the freshwater microalga *Pseudokirchneriella subcapitata* in order to evaluate the aquatic toxicity of nanomaterials. Recent studies have compared the toxicity of nanomaterials of varied physico-chemical properties to algae and investigated the impact of the dispersion protocol on nanomaterial toxicity. Results indicate that the physico-chemical properties of nanomaterials (e.g. composition, size, solubility) are able to influence their toxicity and that exposure and effects depend on media and the approach used to suspend the nanomaterials. In this study *P. subcapitata* was exposed to widely used nanomaterials (silver, single wall carbon nanotubes, multi wall carbon nanotubes and nanocelluloses) at different concentrations (20 - 200 μg/L, for silver nanomaterials and 0.1 to 100 mg/L, for single wall carbon nanotubes, multi wall carbon nanotubes and nanocelluloses), established following pilot studies. A silver salt ($AgNO_3$) control (3 to 17 μg/L) was also tested for comparison purposes with silver nanomaterials. Nanomaterials were dispersed using bath or probe sonication, following well established and published protocols. The growth of *P. subcapitata* was measured following OECD test guideline 201, at different time points (0, 24h, 48h, and 72h), via measurement of optical density (OD) and fluorescence, as well as chlorophyll a, after extraction. Median effective concentrations (EC_{50}) at the different time points revealed that silver nanomaterials were more toxic in terms of growth inhibition than carbon-based NMs, although silver salt was found to be more toxic than the silver nanomaterials. The dispersion method used was found to be a key factor in determining toxicity, with the probe sonicator protocol resulting in higher toxicity. Results from this work indicate the importance in establishing clear standard methods when assessing the hazard of nanomaterials to the aquatic environment.
Key words: nanomaterials, toxicity, sonication and *P. subcapitata*.

TH053
Comparative effect of ZnO-NPs, ZnO bulk and ZnSO4 in the antioxidative defence system of two plant species growing in two agricultural soils in a greenhouse experiment
M. Fernández, INIA / Environment; A. Obrador, Universidad Politecnica de Madrid; D. Gonzalez, ETSI Agronomos / Agricultural Chemistry; M. Babin, C. del Río, INIA / Environment; C. Garcia-Gomez, INIA / Dpto Environment
The nanoparticle (NP) application in food production and agricultural industry is emerging. The use of NPs in agriculture aims mainly to reduce applied amounts of plant protection products, minimize nutrient losses in fertilization and increase yields trough an optimized nutrient management. Therefore, a lot of attention is currently paid to the potential risks arising from the use of these materials in agriculture. In the last years numerous studies have evaluated the phytotoxicity of NPs. However, most of these studies have been performed in hydroponic media over short time periods. These studies do not mimic field conditions and may overestimate toxicity. Phytotoxicity studies under more relevant exposure conditions are necessary due to the importance of the medium and the environmental conditions on the availability and, hence, the toxicity of NPs. Moreover, the studies covering the whole cycle of a planta are desirable to determine the long-term effects. One the most discussed mechanisms by which NPs have toxic effects on organisms is the generation of reactive oxygen species (ROS) which result in oxidative stress to organism. Several studies have shown evidence of oxidative stress on plants exposed to soils contaminated with NPs, but more information is necessary, especially in realistic exposure conditions. The effects of ZnO-NPs on oxidative stress of two plants species of agronomic interest: tomato (*Solanum lycopersicon*) and bean (*Phaseolus vulgaris*) were studied and compared with ZnO bulk and $ZnSO_4$ in a greenhouse experiment. The effects were assessed in two agricultural soils with different pH (an acid soil pH 5.4 and a basic soil pH 8.3) to evaluate the influence of the physicochemical soil properties in the NP toxicity. The soils were spiked with 20 and 225 mg Zn kg^{-1} soil. Additionally, 3 and 100mg Zn kg^{-1} soil were tested for ZnO-NPs and $ZnSO_4$, respectively. Changes on the levels of ROS and proteins, the activity of the antioxidant enzymes (APX, GPOD and CAT), and the effects on lipid peroxidation were measured at different exposure times (15, 30, 60 and 90 days). The results showed that ZnO-NPs could cause oxidative stress in plants under greenhouse conditions. These effects depended on the plant species, soil pH and the exposure time. However, differences between ZnO-NPs, ZnO bulk and $ZnSO_4$ were not observed with some exceptions. This research was funded by the Spanish project RTA2013-00091-C02-01 and RTA2013-00091-C02-02.

TH054
The toxicity of differently coated copper oxide nanoparticles towards the marine blue mussel, Mytilus edulis.
S. Little, Heriot Watt University / Life Sciences; M. Hartl, Heriot-Watt University / Centre for Marine Biodiversity and Biotechnology School of Life Sciences; T.F. Fernandes, Heriot-Watt University / School of Life Sciences
Rapid growth in the field of nanotechnology is continually increasing the potential release of nanoparticles (NPs) into the environment. Although copper oxide nanoparticles (CuO NPs) are widely used within numerous industrial and commercial applications (e.g. batteries, electronic circuits, superconductors, solar energy conversion and gas sensors), their toxicity is still poorly understood in comparison with other metal oxide NPs. As the main recipients of industrial and domestic wastewaters, aquatic systems will inevitably become a sink for CuO NPs throughout their life cycle. Filter-feeders, such as the blue mussel, (*Mytilus edulis*)are widely used in environmental monitoring and are organisms of great interest in regards to the fate and toxicity of NPs within the aquatic environment. This study, funded by the FP7 project, NANOSOLUTIONS, aims to investigate the mode of toxicity exhibited by CuO NPs towards *M. edulis* and the effect of surface coatings upon CuO NP toxicity. *M. edulis* were exposed to core CuO NPs and CuO NPs coated with polyethylene glycol, nitrate and carboxylic acid, for 48 hours at concentrations of 10 and 20 μgL^{-1}. Following exposure, the activity of the antioxidant enzyme superoxide dismutase (SOD) was assessed in *M. edulis* gill and digestive gland tissues to determine whether reactive oxygen species (ROS) were formed as a result of CuO NP exposure, whilst the TBARS (Thiobarbituric Acid Reactive Substances) assay was used to determine whether lipid peroxidation (a product of oxidative stress) had occurred. Additionally, ASCGE (alkaline single cell gel electrophoresis) comet assays were performed on gill and haemolymph cells to assess potential DNA damage caused by CuO NP exposure. It was hypothesised that an increase in CuO NP concentration would lead to an increase in *M. edulis* SOD activity, lipid peroxidation and DNA damage, whilst coatings would influence CuO NP toxicity. Work is currently underway to test these hypotheses.

TH055
Influence of size and surface coating on silver nanoparticles uptake by Gammarus fossarum
K. Mehennaoui, Luxembourg Institute of Science and Technology / Environment Research and Innovation; S. Cambier, T. Serchi, Luxembourg Institute of Science and Technology (LIST) / Environmental Research and Innovation ERIN; G. Francois, LIEC CNRS Université de Lorraine / Campus Bridoux; L. Giamberini, Université de Lorraine, CNRS UMR 7360 / LIEC CNRS UMR; A. Gutleb, Luxembourg Institute of Science and Technology (LIST) / Environmental Research and Innovation ERIN
The increasing production and use of silver nanoparticles (AgNPs) will inevitably lead to their release in aquatic environments where they represent a threat to aquatic species. Therefore, there is still a need to better understand the mechanisms underlying the potential toxicity of AgNPs. Being a very important component of the macroinvertebrate assemblage, *Gammarus fossarum* will certainly be exposed to AgNPs if they reach the water streams. Therefore, *G. fossarum* was selected as a model organism in order to assess AgNPs effects. This study evaluated the acute effects (72h) of three different sizes of AgNPs (20, 40 and 80 nm), either stabilized with citrate (CIT-AgNPs) or coated with polyethylene glycol (PEG-AgNPs), on adult male *G. fossarum*. Tested AgNPs concentrations ranged from 0.5 to 50 ug.L^{-1}. $AgNO_3$ was used to compare AgNPs effects with silver ion effects. $AgNO_3$ was the most toxic compound for *G. fossarum* with an LC50-72h of 1.68 ug.L^{-1}, while none of the studied AgNPs led to lethal effects. Size distribution of CIT-AgNPs and PEG-AgNPs in exposure

media was characterized using nanoparticle tracking analysis. CIT-AgNPs 40 nm and CIT-AgNPs 80 nm were stable whereas CIT-AgNPs 20 nm aggregated to NPs of 53 nm. In contrast, all PEG-AgNPs were stable. Uptake of silver by *G. fossarum*, assessed by ICP-MS, revealed a surface-coating dependent effect with CIT-AgNPs being taken up to a greater extent than PEG-AgNPs. Additionally, a size dependent uptake was observed with CIT-AgNPs 40 nm being more taken up than CIT-AgNPs 20 nm and CIT-AgNPs 80 nm. The same tendency, linking the size to the uptake, was observed for PEG-AgNPs with higher uptake of PEG-AgNPs 20 nm than PEG-AgNPs 40 nm and PEG-AgNPs 80 nm. These results show effects at low and environmentally realistic concentrations of AgNPs for *G. fossarum* and confirm the hypothesis that silver uptake is dependent on size and surface coating of AgNPs.

TH056

The disposition of cationic amino polystyrene nanoparticles in sea urchin immune system cells and their effect on multixenobiotic resistance phenotype

L. Marques dos Santos, Universidade Federal da Paraíba / Departamento de Biologia Molecular; E. Bergami, University of Siena / Department of Physical Earth and Environmental Sciences; K.A. Dawson, University College Dublin / Centre for BioNano Interaction School of Chemistry and Chemical Biology; I. Corsi, University of Siena / Department of Physical Earth and Environmental Sciences

The increasing discard of micro and nanopolymers in the oceans can seriously impact marine ecosystems. Our previous results showed that cationic amino polystyrene nanoparticles (PS-NH_2) induce both embryotoxicity in the sea urchin *Paracentrotus lividus* and immunomodulation in mussel hemocytes. The sea urchin immune system cells (coelomocytes) have been emerged as biosensor in ecotoxicology studies. However, there is no data regarding the effect of polystyrene nanoparticles on these cells. So, the aim of the present study was to investigate the disposition of PS-NH_2 in the sea urchin *P. lividus* coelomocytes and their effect on multixenobiotic resistance phenotype (MXR). The behavior of PS-NH_2 in coelomic fluid medium was assessed by DLS analysis. Coelomic fluid was withdrawn with a 1 mL syringe pre-loaded with anticoagulant solution (500 µL ISO-EDTA). Cells were then centrifuged, resuspended in coelomic fluid, and cell concentration adjusted to 1 x 10^6 cells/mL. Coelomocytes were exposed to PS-NH_2 (1 to 25 µg/mL) and nanoparticle disposition analyzed under fluorescence microscopy. MXR phenotype was investigated by the calcein intracellular accumulation assay. PS-NH_2 was shown to accumulate just in phagocytes and in a time dependent manner. Vibralite cells, red and colorless sphere cells did not exhibit nanoparticle accumulation or plasma membrane adsorption. No cytotoxicity was observed to PS-NH_2 up to 10 µg/mL and until 24 h of cell exposure. However, the PS-NH_2 highest concentration induced cell death (loss of membrane integrity). Moreover, PS-NH_2 exposure - up to 24 h - did not increase calcein intracellular accumulation in coelomocytes. Our data suggest that PS-NH_2 uptake is an active and selective process since only phagocytes internalized the nanoparticles. However, no cytotoxic effect was observed when coelomocytes were exposed to environmentally relevant concentrations. Furthermore, PS-NH_2 exposure, even in the highest concentration, did not affect MXR phenotype. The preliminary results show that exposure to PS-NH_2 up to 10 µg/mL do not impair *P. lividus* immune system cells viability.

TH057

Fate and toxicokinetics of differently coated silver nanoparticles in the deposit-feeding polychaete Capitella teleta

M.B. Nielsen, Department of Environmental Social and Spatial Change; L. Skjolding, DTU / DTU Environment; A. Baun, DTU Environment / Department of Environmental Engineering; A. Palmqvist, Roskilde University / Department of Environmental Social and Spatial Change

Aquatic sediments are believed to constitute an important sink to silver nanoparticles (AgNPs). Knowledge on the effects of AgNPs to sediment-dwelling organisms together with their behavior and fate in these environments are therefore necessary. In this study, the effects and toxicokinetics of differently coated AgNPs (un-coated, polyvinylpyrrolidone-coated (PVP) and mercaptoundecanoic acid-coated (MUDA)) added to sediment in nominal concentrations of 100 μgAg/g dry weight sediment were tested on the sediment-dwelling polychaete *Capitella teleta*. After 15 days of exposure, survival and growth of *C. teleta* was not affected by any of the AgNPs and uptake of the AgNPs was generally low with average weight specific body burdens (WSBB) of 0.140 ugAg/g dry weight worm tissue. After 15 days of depuration in clean sediment, WSBBs had been reduced with more than 50% in all treatments. There was a tendency that MUDA-coated AgNPs were most available for uptake and un-coated AgNPs were least. The fate of the AgNPs in the test system was assessed by measuring the distribution of Ag in the different experimental compartments after 7 and 15 days. The results showed that Ag was mainly recovered in sediment and fecal pellets. Silver concentrations were 2.6 to 3.7 times higher in fecal pellets than in sediment. Fecal pellet Ag concentration was lowest for MUDA-coated AgNPs and highest for un-coated AgNPs. The results suggest that fate and uptake of AgNPs are influenced by particle coating and that *C. teleta* influences the fate of sediment-associated AgNPs.

Subcellular partitioning of size-dependent copper nanoparticle in grass carp (Ctenopharyngodon idella)

W. Chen, Kaohsiung Medical University / Dept Biomedical Science and Environmental Biology; Y. Tsai, Kaohsiung Medical University / Department of Biomedical Science and Environmental Biology

A smaller size of nanoparticles (NPs) may show unique nanoscale properties. To date, the size-dependent waterborne copper nanoparticle (CuNP) toxicity and subcellular partitioning information in the edible freshwater fish are poorly studied. To gain insight into how assumptions regarding size-dependent metal NPs influence their ecotoxicities, this study assessed the mode of action in subcellular detoxification of grass carp (*Ctenopharyngodon idella*) exposed to size-dependent CuNPs. This studycarried out the CuNP subcellular distribution experiments with grass carp from natural populations varying with concentrations and three nanoscales of 25, 40-60, and 60-80 nm. Results showed that smaller size CuNPs had higher accumulation and acute toxicity to freshwater fish. The metabolically detoxified pool (MDP) contained the relatively higher percentages of CuNPs over 37.09 – 72.53%, 37.67 – 66.57%, and 44.21 – 62.26% than those of metabolically active pool (MAP) in 25, 40-60, and 60-80 nm treatment, respectively. We found that metal-rich granules contributed most CuNPs accumulation after CuNPs exposure, indicating that it is a key role on CuNPs detoxification. To our knowledge, it is the first study on size-dependent CuNP subcellular partitioning in freshwater fish. We anticipate that the finding of this study could be used to identify a suitable enzyme or protein that has a strong protection on CuNPs susceptibility and to provide the most potentially promising biomarker to detect CuNPs in the aquatic environments.

TH059

In vitro testing for identification of long term effects of copper oxide nanoparticles in fish cell lines

L. GALBIS, INIA - National Institute for Agricultural and Food Research and Technology / Department of Enviroment; M. Fernandez-Cruz, J. Navas, INIA - National Institute for Agricultural and Food Research and Technology / Environment

Copper oxide nanoparticles (CuONPs) have been widely applied in a number of areas and their antimicrobial activity has opened the door to their use as biocides. As a consequence, there is a high likelihood of release of these NPs into waste streams, and further into aquatic systems. Although CuONPs have been described as toxic for aquatic organisms in a number of studies, these experiments were normally carried out for short periods of time, observing effects on one single generation. However, there is a general lack of knowledge about long term toxic effects of NPs, including CuONPs. In this sense, *in vitro* systems can be a powerful tool to initially determine the mechanisms underlying toxic effects of NPs after prolonged exposure. The objective of this work was to explore the cytotoxic effects of CuONPs on fish cell lines after long-term, low-dose exposures. Two fish cell lines were used in this work: a cell line derived from rainbow trout liver biliary ducts (RTL-W1) and CLC cells, derived from carp macrophages. Cytotoxicity was assessed by means of the alamarBlue, neutral red and CFDA-AM assays. First, cells were exposed to a range of CuONPs (prepared and supplied by PlasmaChem GmbH, Berlin) concentrations for 24 h in order to determine the most appropriate concentrations for longer exposure experiments. Those concentrations used in the 24h exposure most close to the EC50 and EC10 were used in the longer term experiments: 100 and 50 μg/ml, respectively for CLC cells, and 100 and 25 μg/ml, respectively for RTL-W1 cells. Exposure lasted for 21 days and cells were split every 7 days, receiving fresh medium with appropriate concentrations of CuONPs. CLC cells exhibited a very high susceptibility towards CuONPs reaching 100% mortality after 7 days exposure to both concentrations. RTL-W1 viability was not affected after exposure to 25 μg/ml CuONPs for 21 days, but 100 μg/ml caused approximately 90% mortality. TEM analysis of exposed cells evidenced a general disruption of cellular organelles and membranes. The *in vitro* protocol used appears to be useful to study the cytotoxic effects of continuous low-dose exposure to different nanomaterials in a more realistic scenario for prediction of their toxicity in higher tier tests, supporting the 3Rs initiative in the development of alternative ecotoxicological tests. Acknowledgements - This research was supported by FP7-SUN project (Grant Agreement No. 604305).

Ecotoxicity of double-walled carbon nanotubes on Chironomus and Xenopus larvae: monospecific and mesocosm tests

L. Lagier, S. Cadarsi, ECOLAB UMR5245 CNRS UPS INPT; A. Mottier, ECOLAB UMR5245 CNRS; A. Bour, ECOLAB UMR5245 CNRS UPS INPT; L. Verneuil, ECOLAB UMR5245 CNRS UPS INPT / ECOLAB UMR CNRS UPS INPT; J. Silvestre, ECOLAB UMR5245 CNRS UPS INPT; E. Flahaut, C. SARRIEU, CIRIMAT UMR CNRS 5085 UPS INPT; E. Pinelli, L. GAUTHIER, F. Mouchet, ECOLAB UMR5245 CNRS UPS INPT

Carbon-based nanoparticles (CNPs) can be found in many manufactured products and are thus likely to be released in the environment. Among them, double-walled carbon nanotubes (DWCNTs) are well characterized and may be considered as a control nanomaterial to investigate the effects of CNPs on organisms, particularly in the aquatic environment, which is a major receptacle of pollutants.\nThe goal of the present work is (i) to improve the understanding of toxicity mechanisms of a range of concentrations (from 0.1 to 50 mg.L-1 of DWCNTs) on benthic and pelagic organisms by a monospecific approach and (ii) to assess the ecotoxicological risks by using more realistic conditions in a mesocosm, with an interaction between species. DWCNTs are known to interact with constituents of the environment such as natural organic matter (NOM). For this reason, all our tests were performed in the presence of added commercial Suwannee River NOM. Two standardized single-species tests were carried out, respectively, for two aquatic models: *Chironomus riparius* and *Xenopus laevis*. The effect of DWCNTs on monospecific phototroph biofilm of *Nitzschia palea* was tested too. In a second step, these organisms have been grouped within a food chain and exposed to 1 $mg.L^{-1}$ of exposure water. Studied endpoints for chironomids were acute (mortality), chronic toxicity (growth and development delay) and teratogenicity. Furthermore, mortality, growth inhibition and genotoxicity (induction of micronucleated erythrocytes) were studied on *Xenopus*. In monospecific tests, an algal growth delay was measured after 48 h of exposure from $1mg.L^{-1}$. The survival rate of chironomids was significantly impacted from 1 $mg.L^{-1}$. No significant teratogenicity neither growth inhibition was observed. However the frequency of development delay was lower than the negative control from 1 mg L^{-1}. The results didn't show mortality for *Xenopus* but significant growth inhibition and genotoxicity (induction of micronucleated erythrocytes) were noted at 10 $mg.L^{-1}$. Macro-observations suggested that the chronic toxicity could be limited to physical effects (intestinal obstruction and/or abrasive effects and/or nutrients deprivation and/or gill clogging). No effect was observed for all species in mesocosm configuration except a significant growth delay in the chironomid negative control, maybe due to a competition with *Xenopus* for food. Key Words: double-walled carbon nanotubes, ecotoxicity, *Xenopus laevis*, *Chironomus riparius*

TH061

In vitro cytotoxicity of graphene oxide nanosheets on earthworm coelomocytes

J. Kwak, Konkuk University; Y. An, Konkuk University / Department of Environmental Heath Science

By increasing concerns of carbon based nanomaterials that release to terrestrial ecosystem, toxicity of carbon based nanomaterials on earthworms have been steadily investigaed. However, very limited researches on toxicity of graphene oxide nanosheets on earthworm species were reported. This study investigated *in vitro* cytotoxicity of graphene oxide nanosheets on earthworm coelomocytes. Coelmocytes of *Eisenia andrei* were exposed to three different sized graphene oxide nanosheets via *in vitro* and then intracellular esterase activity, oxidative stress, cell size and cell granularity changes were measured by flow cytometer. The results showed that intracellular esterase activities were inhibited and reactive oxygen species were generated. Also cell size was decreased and cell granularity was slightly increased. It indicates that graphene oxide nanosheets caused *in vitro* cytotoxicity on earthworm coelomocytes. *Acknowledgements. This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (2013R1A1A2061386), and the Ministry of Science, ICT and Future Planning (2014R1A2A1A11050513).This research has also been performed as a cooperation project for 2015 Environmental Risk Assessment of Manufactured Nanomaterials funded by the Korea Institute of Toxicology (KIT, Korea).*

Rational design of HMPAA towards environmental safety

C. Venâncio, Department of Biology / Biology; J. Tavares, Department of Biology; F.J. Antunes, University of Coimbra, Department of Chemistry / Department of Chemistry; C. Duarte, University of Coimbra, Department of Chemistry; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; I. Lopes, University of Aveiro / Biology Department CESAM

The production of manufactured nanomaterials (MNM) has been growing since the 90's to fulfill pharmaceuticals, cosmetics, textiles, informatics component, and many others industry and society needs. The present work intended to evaluate the influence of changes in the structural conformation of hydrophobically modified polyacrylic acid (HMPAA) MNMs in their toxicity to freshwater biota in order to identify the MNM variation that is most environmental friendly. Six variations of HMPAA MNMs were obtained by modifying their crosslinked conformation and the insertion position and length of hydrophobic groups. Their ecotoxicity was characterised using the cladoceran *Daphnia magna* as a model organism. Standardised toxicity assays were conducted in order to assess median effect concentrations for: i) survival, ii) feeding behaviour, iii) juvenile growth rate and iv) intrinsic growth rate. Tested concentrations of each HMPAA variation ranged from 0 to 2000 mgL^{-1} (corresponding to the concentration commercially available). Results showed that, at lethal levels, the variation HMPAA2 (with small and large hydrophobic groups positioned alternately along a linear structure) was the most toxic (LC50, 48h= 203.6 mgL^{-1}); while HMPAA5 (sphere structure with hydrophobic groups inside a dense matrix) did not cause any lethal effects after 48h, at 2000 mgL^{-1}. On the contrary, at sub-lethal levels, HMPAA2 was one of the least toxic variations. HMPAA4 (sphere structure hydrophobic groups disposed at the surface) was the most toxic variation for all the sub-lethal endpoints evaluated: feeding ($EC_{50,24h}$= 111.2 $mgL^{-1)}$, somatic growth ($EC_{50,72h}$= 92,4 mgL^{-1}) and intrinsic growth rate (fewest number of neonates per brood, in the first brood and, therefore, lowest number of total neonates and populational growth – *r*). HMPAA 2 and HMPAA 6 (sphere structure with hydrophobic groups inside a tight matrix) reveal to be the less toxic when analyzing the effects in feeding ($EC_{50,24h}$= 249.2 and 281.2 mgL^{-1}, respectively), though, being more toxic to daphnids growth ($EC_{50,72h}$= 276. 8 and 491.2 mgL^{-1}, respectively).The obtained results suggest that different HMPAA structures influences differently the toxicity of these MNM when present at lethal or sub-lethal levels, which challenges the identification of the variation that is more environmentally safe.

TH063

Report on TiO2 nanoparticles ecotoxicity studies in the framework of REACH regulation

E. Bigorgne-Vizade, ANSES / Unit of Chemical Substances Risk assessment Department; J. Lozach, A. Scelo, B. Chion, ANSES / Unit Ecotoxicology Environment Biocides and REACH Regulated products Department; C. Michel, C. Rousselle, ANSES / Unit of Chemical Substances Risk assessment Department

TiO_2 is one of chemical substances registered under REACH regulation. In the specific framework of substance evaluation, a procedure under REACH regulation, we aim to assess risk and safety of producing and using TiO_2. In this work, an inventory of all studies published between 2010 and 2015 related to TiO_2 ecotoxicity studies was carried out. We chose to focus on the 3 main types of aquatic organisms used in regulation: algae, daphnia and fish. They are used in OECD Test Guideline (TG) under REACH and CLP regulation. Thus, 105 studies have been selected in this work: 15 studies with algae, 60 with invertebrates and 30 with fishes. Several parameters have been chosen to select only reliable studies: well-characterized nanoparticles, condition of exposure according to OECD recommendation with the use of replicates, localization/bioaccumulation of nanoparticles. Among all studies selected, most of the Lethal Concentration 50 (LC_{50}), Effective Concentration 50 (EC_{50}) or No Observed Effect Concentration (NOEC) are higher than 1 mg/L. Nevertheless, eight studies on daphnia revealed LC_{50} or EC_{50} below 1 mg/L of TiO_2 anatase, or P25 (70:30; anatase: rutile). Daphnia appears as the most sensitive organism. The parameters involved in the toxic response are: size and crystalline phase of nanoparticles, complexity of medium of exposure, use of UV or light during exposure, increased exposure time compared to the OECD TG. This work highlights the lack of data on characterization of TiO_2 nanoparticles in published ecotoxicity studies and the fact that a fitting of the OECD TG is needed for the nanoparticles testing case.

TH064

Investigation of the potential uptake of magnetofluorescent nanoparticles into human cells

E. Papa, Department of Theoretical and Applied Sciences; J. Doucet, Université Paris Diderot / ITODYS; A. Panaye, Universté Paris Diderot / ITODYS

The creation of magnetofluorescent nanoparticles (MNPs) for the selective labelling of cancer cells represents a field of interest of computational nanotoxicology. The library including 109 MNPs generated by Weissleder and colleagues in 2005, and the related uptake into human cells (i.e. endothelial cells, activated human macrophages and pancreatic cancer cells), was object of several computational studies aiming to predict the uptake behaviour of these NPs from the structure of the organic compounds used as coating. However, due to the structure of the experimental data, all these studies were mainly focussed on the prediction of the uptake into pancreatic adenocarcinoma cells, and almost no effort was provided to try to exploit the experimental information by using, for instance, multivariate analysis, nor to provide additional insight through the identification and analysis of outlier compounds. In this study multivariate analysis (e.g. Principal Component Analysis) was applied to investigate the macro properties of the experimental dataset originally generated by Weissleder and colleagues in order to study the uptake behaviour of the 109 MNPs into different cell lines. Additionally, models based on Quantitative Structure Activity Relationships (QSAR) were developed to predict the uptake behaviour of these NPs into the human pancreatic adenocarcinoma cells and human umbilical vein cells. These models were built on the basis of traditional structural descriptors calculated from the structures of the organic molecules used as coating. These molecules represent the element of structural variation across the 109 MNPs, which all share the same iron nano-core. QSAR models were generated using several linear and non-linear techniques. The statistical performances of these QSARs were investigated, compared, and used to identify common outliers. The models were validated internally and externally on multiple validation and prediction sets. This was performed in order to investigate the internal robustness of the models, the sensitivity of different methods to perturbations of the datasets, as well as to evaluate the predictive ability of the models on MNPs not included in the models development. This study shows how multiple statistical approaches can be applied to investigate complex datasets, and how different QSAR models can be combined to improve the results of models taken singularly.

Polar ecotoxicology: hot issues in cold climates! (P)

TH065
Distribution and origin of selected PCB and PAHs in the Arctic fjords sediments
A. Pouch, Institute of Oceanology / Department of Marine Chemistry and Biochemistry; A. Zaborska, Institute of Oceanology Polish Academy of Sciences; K. Pazdro, Insitute of Oceanology Polish Academy of Sciences
The main objective of the study is to present preliminary results of selected Persistent Organic Pollutants (POPs) concentrations in the Arctic fjords sediments. The extention of knowledge on POPs cycling in the Arctic is important since POPs may be transported over long distances from distant sources, are persistent in the environment and toxic. They tend to accumulate in fatty tissues of organisms, moreover may biomagnify along the arctic food web. POPs are highly reactive particles and are readily sorbed onto sinking organic and mineral particles. Part of them is accumulated by marine organisms and other part is deposited at the sea bottom. Deposited contaminants may be re-introduced to the water column and be again bioavailable for organisms. The study presents the results of polychlorinated biphenyls (PCBs) and polyaromatic aromatic hydrocarbons (PAHs) concentration in sediments collected from Kongsfjord, Hornsund and Adventfjord (eastern Svalbard). These fjords are influenced by different water masses, different rate of glaciers ablation and the intensity of primary and secondary production. In addition, the knowledge on POPs concentrations in the Adventfjord near Longyearbyen may allow to assess the significance of local pollution source. The concentrations of selected polychlorinated biphenyles (CB28, CB52, CB101, dlCB118, CB138, CB153, CB180) and selected polycyclic aromatic hydrocarbons (NAP, FLN, PHE, ANT, FLT, PYR, BAA, CHR, BKF, BAP, DBA, BP, IND) have been measured in sediment cores from selected depth intervals. GC-FID and GC-ECD techniques were used for qualitative and quantitative analysis of polychlorinated biphenyls and polycyclic aromatic hydrocarbons. To assess the origin of PAHs contaminants in sediments, individual components ratios were used. Sediment cores were dated using ^{210}Pb method, therefore the history of POPs accumulation has also been studied. The concentration of Σ7PCBs and ∑12 PAHs in sediments ranged from 0.05 to 1.5 ng/g d.w. and from 33.5 to 463.3 ng/g d.w. respectively. The compounds present in highest proportion were volatile CB28 congener and phenanthrene. The obtained results are also discussed in the context of environmental conditions that may influence POPs accumulation.

TH066
Organochlorine pesticides in archived antarctic ice cores
M. Bigot, Griffith University / Environmental Futures Research Institute; M. Curran, Australian Antarctic Division and Antarctic Climate and Ecosystems Cooperative Research Centre; A. Moy, Australian Antarctic Division; D.C. Muir, Environment Canada / Aquatic Contaminants Research Division; D. Hawker, Griffith University / School of Environment; R. Cropp, Griffith University / Griffith School of Environment; C. Teixeira, Environment Canada / Aquatic Contaminants Research Division; S.M. Bengtson Nash, Griffith University / Southern Ocean Persistent Organic Pollutants Program
Persistent Organic Pollutants (POPs) are toxic ubiquitous anthropogenic substances that have been widely used in agricultural and manufacturing industries since the 1930s. A variety of organochlorine pesticides (OCPs) have been listed as POPs since implementation of the Stockholm Convention which bans or severely restricts the use of POPs into the environment to minimise the hazard they pose. POPs are highly resistant to biodegradation, toxic and bioaccumulative. They are also capable of long-range environmental transport which has led to primarily atmospheric transport of part of the global POP burden to remote Polar Regions. At high latitudes, cold conditions combined with long periods of darkness diminish their volatility and promote their persistence serving to restrict further movement. The polar cryosphere is thus frequently referred to as a “polar sink” for POPs. In the current global warming context, Polar climate may be significantly altered possibly leading to re-volatilisation of historically deposited POPs. Under this scenario, global efforts to moderate human and environmental exposure to these toxic compounds would be altered and Polar Regions would thus act as secondary sources to the atmosphere. Very limited research has been undertaken to gauge the current load of the POP ice reservoir in Polar Regions, particularly in Antarctica. While the release of POPs from melting glaciers has been observed in alpine areas around the world and recent findings also show the presence of POPs in Arctic ice and OCPs in Antarctic glacier melt-water, this study is the first to determine Antarctic continental ice loading of OCPs. Continental ice cores were collected at Law Dome, East Antarctica. They were transferred to a clean stainless steel melting-unit sealed under high purity nitrogen. Melt-water was filtered and subsequently analysed for a suite of 31 OCP analytes. Two early deposition periods were studied 1945-1957 and 1958-1967. Our methods allowed detection of OCPs in both periods studied, particularly for α- and δ-HCH, heptachlor, chlorpyrifos, trans-chlordane, dieldrin, endrin and endosulfan in the dissolved fraction of the meltwater. We observe differences between the two time period studied, sensibly corresponding to usage in Australia where development and use of OCPs began in the mid-1940s, and emissions peaked between 1960 and the mid-1970s. Results and implications will be further presented and discussed.

TH067
Using environmental metabolomics to assess the contribution of oil droplets to dispersion toxicity in pelagic zooplankton Calanus finmarchicus (Crustacea: Copepoda)
T. Størseth, SINTEF / Environmental Technology; D. Altin, BioTrix; T. Nordtug, SINTEF Materials & Chemistry / Applied Environmental Biology and Chemistry; I.B. Øverjordet, SINTEF Materials and Chemistry / Applied Environmental Biology and Chemistry; B. Hansen, SINTEF Materials and Chemistry / Environmental Technology
Toxicity of oil to marine organisms is driven by the presence of dissolved oil components and their partitioning to organisms. In oil dispersions and produced water, a large fraction of the oil components are particle-bound and their potential contribution to toxicity is neglected. For filter-feeding organisms, like copepods, particulate oil may be ingested and as such represent an additional route of exposure. In an attempt to separate the toxic effects of dissolved and dispersed fractions on copepods, we treated them with three concentrations of oil dispersions (D) and filtered oil dispersions to provide a water-soluble fraction (W) without droplets. We also included controls which were fed algae like the exposed copepods, and controls that were not fed (starved). After exposure, copepods were sampled for NMR metabolomics analyses. Initially, Principal Component Analysis (PCA) was performed on the NMR data. The first two principal components (cumulative 69.49%) were dominated by variations in the dataset not associated with the treatments (PC1, 44.45%) and variation which clustered the treatments but not according to dose (PC2, 25.04%). PC3, at 10.67% of the variation separated both high dose dispersion and dissolved treatments from control. In addition the starved group clustered together with these groups. The Kruskall-Wallis rank sum test gave $p< 0.05$ and the following Games-Howell post hoc test gave significant differences for the medium dose dispersion (MD) ($p=0.05$). The high dose dispersion (HD) and high dose water solubles (HW) were also different from the control with means in the same range as MD but with larger variances possibly causing $p>0.05$. The starved group was not significant at the $p=0.05$ level ($P=0.059$) but with a similar mean value as for the MD, HD and HW groups. The PC3 loading profile showed shifts in amino acids which to a large extent had loading values to indicate lower occurrence in high dose exposed and starved groups. Osmolytes taurine and betaine showed the same, whereas homarine had a loading value to indicate higher occurrence in exposed copepods. From these results, exposure to MD, HD and HW fractions was found to give similar global metabolic responses as with starvation as observed by the PCA approach used here. The fact that only the highest dose W group was different from the control whereas both MD and HD were different could indicate that the dispersions are more potent in inducing responses in the metabolome.

TH068
Effects of produced water components on Arctic copepods
I. Salaberria, NTNU University / Biology; I.B. Øverjordet, SINTEF Materials and Chemistry / Enviornmental Technology; S. Bergentz, K. Utne, I.K. Jørgensen, NTNU / Department of Biology; T.G. Nielsen, Technical University of Denmark DTU / National Institute of Aquatic Resources; B. Hansen, SINTEF Materials and Chemistry / Environmental Technology; D. Altin, BioTrix; T. Nordtug, SINTEF Materials & Chemistry / Applied Environmental Biology and Chemistry; A.J. Olsen, Norwegian University of Science and Technology, N-7491 Trondheim, Norway / Department of Biology
Calanoid copepods such as *Calanus finmarchicus*, *C. glacialis* and *C. hyperboreus* are the dominating zooplankton species in the North Atlantic Ocean and the Barents Sea. They store excess energy by accumulating large volumes of lipids during their late development stages before molting into adults. This discrete lipid sac is utilized during periods of low food availability and for reproduction. Exposure to lipophilic water pollutants such as polyaromatic hydrocarbons (PAHs) can lead to the sequestration of these compounds inside the lipid sac. Very low elimination rates of PAHs have been observed in *C. finmarchicus* after exposure to produced water (PW) components warranting further studies on potentially delayed implications of these compounds on survival during diapause and reproductive success. As oil exploration and production moves further north towards the Arctic, the risk of such effects increases and an understanding of the toxicokinetics of PW components on Arctic keystone species is crucial for risk assessment. Key findings of our previous work investigating the effects of petrogenic components on *C. finmarchicus* were revised to provide reference data for our latest project, PWC-Arctic. The main aim is to increase the knowledge on the potential effects of dispersed oil and other PW components on growth, development and reproduction in the Arctic copepods *C. glacialis* and *C. hyperboreus*, thereby supplying parameterized toxicity data for risk assessment of petroleum activity in theArctic. This will be achieved by describing the potential for accumulation (bioavailability) of petroleum related contaminants and dispersed oil droplets from PW and relate this to potential effects on assumed sensitive early life stages.

TH069
Uptake and elimination kinetics for 11 PAHs in Arctic lipid rich copepods
I.B. Øverjordet, SINTEF Materials and Chemistry / Enviornmental Technology;

R. Nepstad, SINTEF Materials and Chemistry / Monitoring and Modelling; I. Salaberria, NTNU University / Biology; B. Hansen, SINTEF Materials and Chemistry / Environmental Technology; T. Nordtug, SINTEF Materials & Chemistry / Applied Environmental Biology and Chemistry; D. Altin, BioTrix; P.R. Gardinali, Florida International University / Chemistry Biochemistry and SERC; A.J. Olsen, Norwegian University of Science and Technology, N-7491 Trondheim, Norway / Department of Biology
Oil exploration and production has recently moved further north towards the Arctic, increasing the potential for exposure of Arctic organisms to polycyclic aromatic hydrocarbons (PAHs) during regular production as constituents of produced water (PW) and from accidental oil spills. Hence, understanding the toxicokinetics of PAHs in Arctic species is increasingly important for environmental risk assessments of regular discharges and damage assessment following accidental spills. The calanoid copepods *Calanus finmarchicus*, *C. glacialis* and *C. hyperboreus* are the dominating zooplankton species in the North Atlantic Ocean and the Barents Sea. They store excess energy by accumulating large volumes of lipids during their late development stages before molting into adults. Previous studies have shown that exposure to lipophilic water pollutants such as PAHs results in an accumulation of these components in *Calanus* species. Traditionally the uptake and depuration kinetics are modelled using one-compartment toxicokinetics. However, previous experimental data on *C. finmarchicus* strongly indicate that elimination of PAHs is much slower than expected based on calculations by state-of-the-art one-compartment toxicokinetic models such as OMEGA. In the present study, the lipid rich developmental stage copepodite V (CV) of the Arctic *Calanus glacialis* was exposed to a filtered dispersion of alkane oil spiked with 11 PAHs for 120 h at 1 °C. The log Kow of the PAHs ranged between 3.3 for naphthalene and 5.78 for chrysene. A 120 h depuration period in clean seawater followed the exposure period, and samples for body burden analyses were taken at regular intervals during both the exposure and the depuration periods. Models developed to fit to the uptake data were used to predict depuration kinetics for individual compounds. Several of the PAHs, especially the heavier fluoranthene, pyrene and chrysene, showed approximately 100 % retention after the 120 h depuration period, substantial deviations from the predictions by the one-compartment models. The slow depuration of PAHs in lipid rich Arctic copepods demonstrated in this experiment indicates that stored PW components may be more available for transfer to progeny, as well as having a higher potential for transfer to higher trophic levels than previously anticipated.

TH070

Enzyme expression in Antarctic krill (Euphausia superba) exposed to p,p'-DDE

A. Dawson, Griffith University; W. Huston, University of Technology Sydney / School of Life Sciences; A. Poulsen, Florida State University / Department of Earth Ocean and Atmospheric Science; S.M. Bengtson Nash, Griffith University / Southern Ocean Persistent Organic Pollutants Program
Despite the apparent pristine nature of Antarctica and it's remoteness to industry, Persistent Organic Pollutants (POPs) have been detected in Antarctic biota since the 1960s. Antarctic krill from the Southern Ocean, an important Antarctic prey species, have been found with notable concentrations of POPs, including the pesticide, DDT and its most common metabolite, *p,p'*-DDE. Several organism-level responses have been observed in krill following sublethal *p,p'*-DDE exposure. However, nothing is currently known about the underlying subcellular mechanisms of these responses, or the metabolism of *p,p'*-DDE in Antarctic krill. The purpose of this study was to examine the metabolic response of Antarctic krill exposed *p,p'*-DDE. Krill were examined for Glutathione S-transferase (GST), Glutathione peroxidase (GPx) and Acetylcholinesterase (AChE) activity in response to *p,p'*-DDE exposures ranging from 1-20 μg/L. None of the enzymes responded to *p,p'*-DDE in a concentration dependant manner. GST activity slightly increased for all doses but only the highest exposure induced a significantly increase. GPx followed a similar trend although none of the concentrations induced a significant increase in activity. Krill exposed to these concentrations exhibited signs of toxicity, most likely due to neurological impairment. This indicates that Antarctic krill exhibit a limited capacity for GST facilitated metabolism of *p,p'*-DDE at these concentrations. AChE decreased in three of the four treatments, but actually increased for the 10μg/L exposure, suggesting that the responses were not dependent on *p,p'*-DDE but may have actually been caused by an underlying factor. Thus AChE inhibition is not an indicator of organochlorine induced neurological toxicity in krill. Based on the GST and GPx activity measured in this study, krill appear not to have the ability to detoxify themselves of *p,p'*-DDE. This may indicate that this species is highly sensitive to this pollutant in the environment and possibly similar POPs. As *p,p'*-DDE is commonly detected in Antarctic biota, the apparent lack of detoxifying ability of Antarctic krill is troubling and should be examined further.

TH071

Baseline energy-budget model for the marine copepod Calanus finmarchicus

T. Jager, DEBtox Research / Dept of Theoretical Biology; I.B. Øverjordet, SINTEF Materials and Chemistry / Enviornmental Technology; K.M. Hammer, SINTEF Materials and Chemistry; D. Altin, BioTrix; A. Olsen, Norwegian University of Science and Technology; T. Nordtug, SINTEF Materials & Chemistry / Applied Environmental Biology and Chemistry; B. Hansen, SINTEF Materials and Chemistry
Calanoid copepods form an important part of the marine zooplankton, and are exposed to stressors such as pollution resulting from oil and gas exploration. Mechanistic models are needed to interpret the effects of such stressors, and to predict the impact on the copepod life histories under realistic environmental conditions. Dynamic Energy Budget (DEB) models are well-suited for this task as they can provide an integrated framework covering all life-history traits over the entire life cycle of a species. Furthermore, these models are (relatively) simple, in principle not species specific, and easily linked to population models. Copepods, however, have several features in their life cycle which require further consideration in energy-budget models. Firstly, they develop through six naupliar stages, which deviate in morphology from the later six copepodite stages, and the first two stages do not feed. Secondly, copepods follow determinate growth, and stop growing after their final moult to adulthood. And thirdly, many copepods (especially those species from higher latitudes) build up a considerable lipid storage during the last few copepodite stages to survive adverse environmental conditions and to fuel the reproduction process. Before we can consider the effects of stressors on the life history, we need to develop a baseline model to capture these deviations from the standard DEB models. In this contribution, we report on our progress in modelling the growth, development and lipid storage in *Calanus finmarchicus*, a common species in the Northern Atlantic Ocean and expanding up into the Arctic. Once this model is established, it can serve as a platform to interpret the effects of toxicants and other stresses, and as a basis for extrapolating to other high-latitude copepod species.

TH072

Exposure of ovigerous female copepods to oil causes transcriptional responses in offspring - Maternal transfer of PAHs?

B. Hansen, SINTEF Materials and Chemistry / Environmental Technology; A. Tarrant, Woods Hole Oceanographic Institution; I.B. Øverjordet, SINTEF Materials and Chemistry / Applied Environmental Biology and Chemistry; I. Salaberria, NTNU University / Biology; K.E. Read, SINTEF Materials and Chemistry / Applied Environmental Biology and Chemistry; D. Altin, BioTrix; A.J. Olsen, Norwegian University of Science and Technology, N-7491 Trondheim, Norway / Department of Biology; T. Nordtug, SINTEF Materials & Chemistry / Applied Environmental Biology and Chemistry
Copepods of the *Calanus* genus have a large potential for accumulating oil components during exposure due to their high lipid content and impressive filtration rates, and they have been shown to filter and ingest oil droplets during exposure. Female copepods produce eggs at the expense of their discrete lipid sac, suggesting either a remobilization of lipid-accumulated oil components and/or a direct transfer route of such contaminants to offspring. In an attempt to assess the potential for maternal transfer of oil components we exposed ovigerous female copepods (*Calanus finmarchicus*) to filtered and unfiltered oil dispersions for 4 days and collected their eggs the 3-6 days following the end of the exposure period. They were reared in clean water through to the late naupliar stages (N5-6) and collected for RNA extraction and preparation of libraries for high-throughput transcriptome sequencing. Differentially expressed genes were identified through pairwise comparisons between treatments. Expression of 173 genes was altered in response to dispersion exposure, 184 in response to the filtered dispersion, and 35 genes were affected by both treatments. Among the differentially expressed genes, several have known roles in responses to chemical stress including Phase I enzymes (oxidizing, Cyp2J-like), Phase 3 enzymes (exporting, multidrug resistance proteins), antioxidants (thioredoxin, xanthine dehydrogenase), chaperones (Hypoxia upregulated protein, quinone oxidoreductase), and components of the inflammatory response (phospholipase A2 activating protein).

TH073

Plastics in the Antarctic environment (PLANET project): preliminary observations of microplastics in the Antarctic biota

e. bergami, University of Siena / Department of Physical Earth and Environmental Sciences; M. Grattacaso, University of Siena / Physical Earth and Environmental Sciences; H. Leslie, IVM- VU University / Chem Biol; S. Olmastroni, University of Siena; I. Corsi, University of Siena / Department of Physical Earth and Environmental Sciences
Several studies estimates that trillions of plastics are floating all over the oceans and thus recognized as a global environmental problem and one of the most important threats for marine ecosystems. Although Antarctica has been historically seen as a pristine region, it might be reached by plastic debris due to the increase of fishing and tourism but also by transport from transboundary sources which can cross the Antarctic Polar Front. Macroplastics (> 1 cm) have been surveyed by sight in the Southern Ocean since 1980s and more recently reported around Antarctica (South Georgia), therefore their presence and high persistence might pose a serious concern for this fragile marine ecosystem. Smaller plastic pieces in the micro and nanosize range can be uptaken and retained by Antarctic organisms, leading to bioaccumulation, toxicity but also trophic transfer to top-predators with potential impact for marine ecosystems as a whole. Up to date, no information for Antarctic marine ecosystem on the presence of micro and nanoplastics are available. While microplastics are quite well studied,

fate and impact of nano-sized plastics in the marine environment are almost unknown and are raising concern due to increasing abundance in water column and their properties which could imply toxicity to marine biota. Therefore, studies in remote areas as Antarctica are urgently needed in order to understand their distribution and take measures for the conservation of one of the last pristine areas in the world. The aim of the PLANET project is to study *i*) the presence of micro and nanoplastics in Antartic marine environment and *ii*) the impact on marine species in terms of bioaccumulation, trophic transfer and toxicity. Several biological samples collected in the last 10 years on the Antarctic Ross Sea area close to the Italian Antarctic Base "Mario Zucchelli" and from a penguin colony at Edmonson point were processed for identifying the presence of micro and nanosized polymers. Samples of phytoplankton, krill, scallop, fish, penguin (blood and feaces) and sea bird (skua) were homogenized, filtered and analysed by light microscopy and by FTIR and Raman for polymer types identification. Fibers and foils were the most abundant and appears to be common across a range of different species and biological samples while sphere were present only in selected samples. Sources, trophic transfer and size able to exert toxicity towards Antarctic marine species are reported and discussed.

TH074

DNA damage in arctic avian predators: baseline, sensitivity to stress and association to contaminant exposure

A. Haarr, K. Hylland, University of Oslo / Department of Biosciences; G. Gabrielsen, Norwegian Polar Research Institute; J. Bustnes, Norwegian Institute for Nature Research, NINA; D. Herzke, Norwegian Institute for Air Research NILU; K. Borga, Department of Bioscences, University of Oslo / Department of Biosciences

The polar region functions as a pollution sink where chemicals produced and used in southern latitudes are transported and deposited. Seabirds are exposed to an increasing load of stress due to a warming climate, loss of habitat, changes in their marine food sources and also pollution. Seabirds are important study organisms in ecotoxicological studies and they are considered good indicators of the oceans health as they inhabit different trophic levels, have different physiological adaptions and may be sensitive to human induced environmental changes. While the legacy pollutants are decreasing in the environment, they are still found in higher concentrations compared to newer compounds that are emerging due to increased chemical use to meet demands from our modern society. Organohalogen contaminants are known to elicit a wide range of negative effects on wildlife, such as effects on enzyme-, immune-, endocrine- and vitamin systems. The field of genotoxicity can provide new information about the effect that pollutants have on an organism's DNA. DNA damage can be measured as a result of different stressors on an organism, and may be an interesting biomarker as an organism's genome is vital for a wide range of different functions and systems. The comet assay is a well-established method to quantify single- and double strand breaks in the DNA; it is relatively easy and inexpensive, and a sensitive tool for assessing DNA damage. The comet assay is used in human toxicology on different types of cells, on other mammals, crustaceans, mollusks and fish. However, few studies have been conducted using the comet assay in assessing genotoxicity in avian wildlife and thus, little is known regarding baseline DNA damage in various species, the sensitivity to oxidative stress-induced damage and the relationship between contaminants and degree of DNA damage. These knowledge gaps are addressed in the present study, focusing on the arctic seabirds the common eider, black-legged kittiwake, arctic skua, and glaucous gull. Field work was conducted in June- July 2015 in Kongsfjorden in Ny Ålesund, Svalbard, and the four different species were caught during incubation or early hatching period. Biometric data was measured and blood samples were taken. Data presented at the SETAC meeting will be levels of DNA damage (baseline and sensitivity) in the different species, and the relationship to drivers behind the observed results; contaminant levels, body condition or other factors.

TH075

Determination of mercury speciation and isotopic composition of Antarctic seabird tissues: Tracing Hg trophic sources or metabolic response?

M. Renedo Elizalde, Université de La Rochelle / LIENSs UMR; D. Amouroux, Laboratoire de Chimie Analytique Bio Inorganique et Environnement, UMR CNRS IPREM5254, University Pau.; Z. Pedrero Zayas, LCABIE-IPREM UMR 5254 CNRS-UPPA; Y. Cherel, CEBC CNRS Université de la Rochelle UMR; E. Tessier, LCABIE-IPREM UMR 5254 CNRS-UPPA; S. Bérail, LCABIE-IPREM UMR CNRS-UPPA; P. Bustamante, LIENSs CNRS & Université de la Rochelle UMR 7266 / LIENSs

Mercury (Hg) is considered a globally distributed pollutant of major concern for humans and wildlife especially under its form of monomethylmercury (MMHg), which is capable to accumulate in the organisms and biomagnify within the food webs. In the last decade, the measurement of Hg isotopic mass dependent and independent fractionation (MDF and MIF, respectively) has become an essential tool in identifying sources of Hg and quantifying its reactivity within the different compartments of the environment. Although Antarctic and sub-Antarctic environments have been usually perceived as remote areas untouched by anthropogenic pressure, they are reached by contaminants through ocean circulation and atmospheric transport. However, Hg contamination in this region remains largely unknown, and new studies combining Hg speciation and isotopic approaches are required to elucidate this question. Seabirds, as upper predators, are exposed to large quantities of Hg via food intake and have been identified as effective biomonitors of Hg marine contamination. This work is focused in the evaluation of Hg sources, trophic transfer and metabolic pathways by analyses of different tissues of seabirds from the French Southern and Antarctic Lands (Southern Indian Ocean). Organs (pectoral muscle, liver, brain and kidney), feather and blood samples were studied by the combination of Hg isotopic composition analyses by Multicollector(MC)-ICP-MS and Hg speciation analyses by species-specific Isotope Dilution Gas Chromatography-ICP-MS (ID-GC-ICP-MS). An optimisation and validation of the sample preparation procedure was previously accomplished. Four seabird species with contrast feeding ecology were studied: Antarctic prion (zoo-plankton eaters), white-chinned petrel and king penguin (mesopelagic fish consumers), and northern giant petrel (other-seabird meat and carrion eaters). Significant differences in MDF signatures were observed between tissues for all the species, in particular for Antarctic prions. An enrichment in lighter δ^{202}Hg values was observed from feathers to muscles and livers which could be attributed to inter-organ transport or metabolic processes. Hg MIF values differed widely between organs which could be the result of different MMHg sources. This study evidences the great potential of the combination of Hg speciation and isotopic composition analyses using seabird tissues to investigate Hg sources and metabolic pathways at different levels of the marine food web.

TH076

Contaminant exposure in arctic foxes (Vulpes lagopus) from Svalbard in relation to climate-linked changes in feeding habits and food availability

H. Routti; E. Fuglei, M. Andersen, The Norwegian Polar Institute; I.G. Hallanger, UiT The Arctic University of Norway / AMB; L. Hanssen, NILU Norwegian Institute for Air Research; M. Konig, . Pedersen, The Norwegian Polar Institute; A. Polder, Norwegian University of Life Sciences / Department of Food Safety and Infection Biology; N. Yoccoz, UiT The Arctic University of Norway

The arctic fox is a circumpolar species and the population inhabiting Svalbard is among the highest contaminated apex predators of arctic ecosystems. At Svalbard arctic foxes are top predators and scavengers that depend on both the terrestrial and marine food web. Climate-induced variability is likely to influence arctic fox diet through availability of reindeer carcasses and sea ice cover. In the present study, temporal trends of a wide range of contaminants in arctic fox (*Vulpes lagopus*) from Svalbard, Norway, sampled 1997-2014, were investigated in relation to feeding habits and food availability. Stable isotope of carbon (Î^{13}C) was included as a proxy for marine versus terrestrial feeding habits. Annual number of carcasses of Svalbard reindeers (*Rangifer tarandus platyrhynchus*) and sea ice cover (access to seals) were used as proxies for food availability. Liver concentrations of all compounds increased with increasing intake of marine food. Reindeer mortality was negatively related to concentrations of perfluorocarboxylic acids (PFCAs), HCB and THg, while perfluoroalkyl sulfonates (PFSAs), Ƭ-HCH and THg concentrations increased with sea ice cover. Linear models revealed that concentrations of PFCAs and THg adjusted for Ᵽ^{13}C, reindeer mortality and sea ice cover increased over time, while no trend was observed for hexachlorobenzene (HCB) and beta-hexachlorocyclohexane (Ƭ-HCH). Adjusted concentrations of PFSAs, polychlorinated biphenyls (PCBs) and their hydroxylated metabolites (OH-PCBs), chlordanes, p,pH_-DDE, mirex, PBDEs decreased over time. The present results suggest that climate-related changes in feeding ecology influence contaminant exposure in arctic foxes.

TH077

In vitro and in silico techniques as a tool to assess effects of pollutants on polar bear energy homeostasis

H. Routti; M. Berg, University of Bergen; A. Goksøyr, University of Bergen / Department of Biology; M. Harju, NILU Norwegian Institute for Air Research; L. Helgason, UiT The Arctic University of Norway; T. Fink, Aalborg University; K. Kristiansen, UiT The Arctic University of Norway; R. Lille-Langøy, M. Rusten, University of Bergen; I. Sylte, University of Tromso; L. Øygarden, University of Bergen

Prolongation of ice-free summer seasons will lead to longer fasting periods of polar bears, which use sea ice as a platform for hunting. Fasting is physiologically demanding and requires optimal control of energy homeostasis. Peroxisome proliferator-activated receptors (PPARs) play a central role in regulating energy homeostasis. We hypothesize that contaminant exposure in polar bears may affect their energy homeostasis and thus decrease their ability to respond to climate change. To explore our hypothesis, we used multiple parallel approaches including in silico and in vitro techniques to investigate effects of contaminant mixtures on energy homeostasis of polar bears. Binding of over 600 new and legacy contaminants to polar bear PPARs was studied using *in silico* docking and scoring methods. The results indicate that several brominated and fluorinated compounds have a potential to bind polar bear PPARs. Activation of polar bear PPARs by emerging and legacy chlorinated and brominated contaminants has been studied using *in vitro* cell lines. The results suggest that several common pollutants found in polar bears and humans have either weak agonistic or antagonistic potential towards polar bear PPARs. Synthetic mixtures reflecting the concentrations of contaminants found in polar bear adipose tissue suppressed polar bear and human PPARγ activity as well as PPARγ-mediated accumulation of lipids in mouse fat cells. Lipid accumulation in the mouse fat cells, through PPARγ-independent pathways was not affected following exposure to the synthetic mixtures. Contaminant mixtures extracted from polar bear tissues enhanced lipid accumulation in the mouse fat cells. We have also isolated polar bear stem cells from their adipose tissue and established a method to study lipid accumulation and mRNA expressions in cells exposed to mixtures of contaminants. In addition, we have determined the presence of a wide range of new and legacy compounds in polar bear fat samples by using non-target and target analyses.

Soil and water contaminants: evaluation, biomonitoring and bioindicators for effective management (P)

TH078

The validation of analytical methods as an evaluation tool of research results reliability

E. Ollivier, A. Jaulin, V. Grondin, A. Trouvé, INRA Institut National de la Recherche Agronomique / UMR ECOSYS Platform BiochemEnv; N. CHEVIRON, INRA/AgroParisTech / UMR ECOSYS Plateforme BiochemEnv

Biochem-Env is a platform for analytical biochemistry created in 2012 by INRA with the support of the program "Investissements d'avenir" ANAEE-France. The mission of Biochem-Env is to provide facilities for the biochemical characterization of natural environments (enzyme activities in soils and sediments) and associated macrofauna (enzyme activities, phospholipid fatty acids, terrestrial and benthic macrofauna biomarkers), as well as lipidic biomarkers (PLFAs). Partner in research projects, the platform must produce traceable analytical data with high level of confidence. INRA's quality policy requests the validation of analytical methods when laboratories use non-standardized ones and methods used outside the scope of application of the dedicated norm. For intra-laboratory validation of quantitative analytical methods, the INRA's Quality Guidelines for research and experimental units (2013) recommends "the accuracy profile"method according to the NF V03-110: 2010 standard. This approach has the advantage of providing an overall statistical method combining trueness and precision *by* simple and graphic interpretation and allowing a rapid decision. Furthermore, it enables the determination of quantification limits, the scope of the application of the method and the estimation of uncertainty associated with the results. The process of analytical method validation allows establishing fitness for purpose by the interpretation of criteria in relation to the scientific objectives. The objective of this study was to evaluate and validate the performance of such an internally developed method applied to a set of species of terrestrial and benthic macrofauna. We expressed in particular interest in protein determination method by the bicinchoninic acid, using a commercial kit. The method was applied to 7 earthworm species, one of beetle, spider and gammarids. The validation method helped us to assess the matrix effect and to improve the steps for sample preparation and analysis. It also pointed out the importance of an experimented analyst to apply the analytical method.

TH079

Selecting optimized methods for environmental monitoring in the CCS project

H. Lee, Korean Basic Science Institute / KBSI Seoul Center; S. Jeong, Korea Basic Science Institute; H. Yoon, Korea Basic Science Institute / Seoul center

The chemical monitoring on concerned substances in the environmental samples including soils and waters is generally through analyses in the laboratories. It is axiomatic that intensive quality assurance and control (QA/QC) programs should be conducted to reduce analytical failures, specifically considering that the monitoring data plays a key role to secure the public acceptance in carbon capture and storages (CCS) projects. As the one of QA/QC activities, we've been preparing the method-selecting chart on soil and water analyses. By the methods, the confidence range of concentration and applicable matrix are various. In addition, scales of matrix interference and public susceptibility to chemical changes are different as well as concentration of each element or substances by the environmental medium. Therefore, we aim at provision of simple but secure method-selecting chart considering the matrix properties including total dissolved solids (TDS) and the expected concentrations of interfering substances. The result of this study will be an analytical-method-selecting chart for the Korean CCS project, K-COSEM (Korean CO_2 Storage Environmental Management). The substances included the chart are selected from previous results of natural analogue studies and the foreign CCS projects. The samples from CCS project can be classified into two categories by matrix: (a) soils, and (b) waters. And the chemical concentrations of each matrix from CCS can have greatly wide range due to the characteristics of each substance and released CO_2 levels. The previous monitoring data obtained from the studies on natural analogue sites and CO_2-leakage test sites also play as a yardstick as well as confidence-range of each method.

A bioassay battery for the ecotoxicity assessment of foaming agents containing anionic surfactants

P. Grenni, National Research Council of Italy (CNR) / Water Research Institute; A. Barra Caracciolo, National Research Council of Italy / Water Research Institute; L. Patrolecco, Water Research Institute-National Research Council / Water Research Institute; N. Ademollo, National Research Council of Italy / Water Research Institute; S. Ludovica, National Research Council of Italy / Water Research Council; M. Mingazzini, National Research / Water Research Institute; M. Palumbo, Water Research Institute, CNR; E. Galli, V. Muzzini, C. Polcaro, E. Donati, National Research Council of Italy / Water Research Institute; I. Lacchetti, Istituto Superiore di Sanità (ISS) / Department Environment and Primary Prevent Unit Soil and Waste; G. Mininni, Italian National Research Council / Water Research Institute

Alkylethoxysulfates (AES) surfactants are widely used in numerous industrial applications, as mechanized drill and fracking. They are present in commercial foaming products as their main components, together with different and sometimes not reported additives. In spite of their high volume utilization, very few data concerning the occurrence, fate and effects of AES on ecosystems have been published so far. The objective of this study was to evaluate the ecotoxicological effects of two commercial foaming products containing, as the main substance, the anionic surfactant sodium lauryl ether sulfate (SLES). In order to evaluate the EC_{50} values of the two commercial foaming products, they were initially subjected to ecotoxicological tests with aquatic and terrestrial organisms (Microtox test with *Vibrio fischeri*, *Pseudokirchneriella subcapitata* toxicity test and germination and growth test with *Lepidium sativum*). Then two soils with different geopedological characteristics were conditioned with the commercial foaming agents at the same concentrations used for mechanized drills and used for an experimental microcosm set-up. Soil sub-samples were collected at different times (0, 7, 14, 28 days) and soil elutriates were produced for assessing the effects of the foaming agentsboth on the previous tested organisms (*Vibrio fischeri, Pseudokirchneriella subcapitata, Lepidium sativum*) and on other two, performing the Fish Embryo Toxicity Test (FET) with *Danio rerio* and *Daphnia magna* toxicitytest. The results of the five tests were then compared with SLES residual concentrations, determined by MBAS spectrophotometric method both in the elutriates and in ASE soil extracts.

Environmental safety assessment of biomass process streams

K. van Gestel, VU University Amsterdam / Ecological Science; B. Pieterse, Biodetection Systems BV; D. Giesen, DELTARES; J. Legradi; R. Vooijs, Vrije Universiteit Amsterdam / Department of Ecological Science; B. van Vugt-Lussenburg, BioDetection Systems; D. Roelofs, Vrije Universiteit Amsterdam / Department of Ecological Science; E. Roex, DELTARES; E. Swart, T. de Boer, Vrije Universiteit Amsterdam / Department of Ecological Science; M. Lamoree, VU University Amsterdam / Institute for Environmental Studies

The bio-based production of chemicals provides opportunities for developing a safer and green chemistry. Growing biomass on contaminated soils may allow for the use of otherwise neglected land, but it may also lead to uptake and introduction of hazardous chemicals in the production chain. The (pre)treatment of biomass may lead to the formation of potentially hazardous intermediates. The presence of hazardous chemicals may not only threaten the production process itself, but it may also pose a risk to workers in the industry as well as to the environment receiving waste materials. Within the Dutch BE-Basic programme, the dRISK project (Integrated effect-based risk management for sustainable bio-based production processes) is developing tools and strategies for assessing the potential hazard of biomass streams, using bioassays based on living organisms or cells. The panel of bioassays comprises human cell lines, zebrafish embryos, daphnids, springtails and enchytraeids, and is predictive for various adverse outcomes and groups of organisms at risk. By combining chemical separation and identification techniques with the bioassays, so-called Effect-Directed Analysis, possible chemical stressors that are responsible for toxic effects can be identified. Since chemicals may be strongly embedded in the biomass, not being available and therefore posing little hazard, two extraction approaches were developed. The first one applies total chemical extraction followed by testing in the various bioassays to determine potential toxicity of biomass materials. The second approach applies passive sampling methods that extract only the available chemicals from the biomass followed by exposing the bioassays using passive dosing. The latter method is based on equilibrium partitioning and ensures that the organisms are exposed to realistic available concentrations. This also allows exposing all organisms to the same activity of potentially hazardous chemicals. This presentation will show how the tools developed in dRISK are applied to biomass obtained from the processing of verge grass, as an instrument for the safety assessment of bio-based production processes. The verge grass was harvested from road sides and as a consequence may be contaminated with metals, PAHs and other known and unknown pollutants. It therefore is an interesting substrate for bio-based production as it is unsuitable for other uses, like cattle feed, but it may also pose some of the risks outlined above.

TH082

An approach to choose the most relevant time of exposure for biomarker measurement in earthworms exposed to pesticides

E. Ollivier, INRA Institut National de la Recherche Agronomique / UMR ECOSYS Platform BiochemEnv; C. Pelosi, INRA Institut National de la Recherche Agronomique / UMR ECOSYS; C. Mougin, INRA (Institut National de la Recherche Agronomiqu / UMR ECOSYS; N. Cheviron, INRA Institut National de la Recherche Agronomique / UMR ECOSYS Platform BiochemEnv

Biomarker measurements on organisms known as bioindicators are considered as good tools to assess both environmental quality and functioning. Earthworms, by their ecological functions and sensitivity, are relevant organisms to evaluate the quality of soils disturbed by human activities. Despite a great amount of experiments intended to study xenobiotics effects on the physiology of soil organisms under controlled conditions, no clear trend emerged concerning the responses of biomarkers. Owing to the high heterogeneity observed in laboratory protocols (species used as models, types and concentrations of contaminants, time of exposure, analysis methods) can even lead to contradictory results. The aim of this study was to underline the kinetic responses of biomarkers involved in earthworm physiology (defense against oxidative stress, detoxification mechanisms and energy reserves) within time. Our main hypothesis was that the conditions and particularly the time of exposure strongly influenced the results obtained in these studies. Here we provide the most relevant interval of time exposure for each biomarker. Earthworms of the species *Aporrectodea icterica* were exposed to pesticides in laboratory conditions, at realistic agronomic dose or agronomic dose x 10, alone or in a mixture. Earthworms were placed in microcosms containing contaminated soil, during periods of 2, 4, 7, 10, 14 and 21 days before biomarkers analysis. The two selected pesticide were an insecticide of the pyrethrinoids family, CYTHRINE MAX ® (Cypermethrin) and a fungicide of the strobilurin family, AMISTAR ® (Azoxystrobin), commonly applied in cereal crops. We will present the results of the kinetic responses for each selected biomarkers (catalase, glutathione-S-transferase, superoxide dismutase, proteins …), time of exposure and pesticide dose within time. We will also identify the most suitable period to their measurement.

TH083

Effect of the type of contamination and land use on soil enzymatic activities. Results of the French "Bioindicator program"

N. CHEVIRON, INRA/AgroParisTech / UMR ECOSYS Plateforme BiochemEnv; C. Marrauld, INRA Institut National de la Recherche Agronomique / UMR ECOSYS; I. gattin, Esitpa / Unité ARGITERR laboratoire BioSol Mont Saint Aignan; K. Mougin, INRA (Institut National de la Recherche Agronomiqu / UMR ECOSYS

Since many decades, enzymatic activities are used to assess the effects of land use changes, agricultural practices and soil contamination on soil functioning. A lot of studies point out contradictory results depending notably on the methodology used, as well as soil characteristics… To overcome the lack of consensus concerning indicators available to assess soil quality and functioning, the national research programme "Bioindicator" (overseen by ADEME) was set up in France to develop and assay biological indicators (2006–2012). We aimed at standardizing and emphasizing the number of biochemical measurements, and developed miniaturized colorimetric methods to obtain a great enzymatic dataset. Thirteen activities (from three laboratories) were measured within this programme, in 47 modalities of 13 experimental sites differing in terms of land use (Corine land cover), contamination type – Polycyclic Aromatic Hydrocarbures or metals – and pollution levels (Vibrisse 8^{th} decile). This dataset allows an analysis of the effect of atmospheric or added contamination gradients on the enzymatic activities. Our objectives are to point out the sensitivity of enzymes for each type of pollution and land use, to offer the most appropriate panel for a sensible analysis. Data were analysed for the all datasets, each site and each land use. Our main conclusions are as follows: enzymes are more sensitive to metallic contamination than to organic ones; enzymes are good indicators of metal bioavailability; Alkaline phosphatase and Arylamidase are the most relevant enzymes to assess the effect of soil contamination

TH084

The significance of soil microalgae and cyanobacteria to assess pesticide stresses, in agricultural soils

O. Crouzet, C. Marrauld, INRA Institut National de la Recherche Agronomique / UMR ECOSYS; P. Maron, INRA Institut National de la Recherche Agronomique / UMR Agroécologie Platform GenoSol; F. RIMET, INRA UMR CARRTEL / UMR CARRTEL; C. Mallet, Université Blaise Pascal / UMR LMGE; C. Mougin, INRA (Institut National de la Recherche Agronomiqu / UMR ECOSYS; A. Bérard, INRA Institut National de la Recherche Agronomique / UMR EMMAH

Standardized soil microbial indicators, used to assess the impacts of agricultural practices and/or contaminations, lack of sensitivity and genericity against pesticide stresses, especially for herbicides. Soil photosynthetic microorganisms, mainly represented by micro-algae (chlorophyceae, xanthophyceae and diatoms) and cyanobacteria, can growth in soil surface. So, they could be an original microbiological model for herbicides risk assessment in agricultural soils. Nevertheless, their structural and functional biodiversity and the environmental factors influencing their communities are still largely unknown. Then, to improve our understanding of these photosynthetic microorganisms, we need to 1) develop biochemical and molecular methods to characterize their activities and genetic diversity and 2) analyse their responses to herbicides in agricultural soils. Several methodologies commonly used for aquatic systems were adapted to soil. Cultural approaches are still helpful to isolate edaphic species for further ecotoxicological tests and barcoding approaches. Photosynthetic pigments can provide biomass (chlorophyll-*a*) or structural (pigment diversity) indicators. Several genetic markers from aquatic studies were successfully applied on soils samples, but a current limit is the lack of databases of these specific genetic markers. Toxic effects on photosynthetic microbial biomass and diversity have been evidenced at doses close to recommended field rates, throughout field and microcosm approaches. The comparison of the responses of photosynthetic microbial communities, between different cropping systems (organic vs. conventional), highlighted a tolerance increase for some herbicides in conventional soils. Genetic diversity characterization of micro-algal and cyanobacterial communities in these cropping systems, provides further results to identify taxa relating to tolerance. Then, various genus of microalgae and cyanobacteria have been identified for their high sensitivity to herbicides. Overall, micro-algal and cyanobacterial communities showed a higher sensitivity to herbicide in soils, compared to commonly studied bacterial and fungal community. These innovative investigations demonstrate the suitable issues of soil photosynthetic microorganisms as indicators reporting non-target impacts of herbicides on soil biodiversity and functioning. Prospects for monitoring remediation of polluted soils (heavy metals, HAP) should be considered.

TH085

Use of the crustacean Gammarus fossarum in biomonitoring survey and trophic transfer of protozoa Toxoplasma gondii and Cryptosporidium parvum

A. Bigot, M. Palos Ladeiro, A. Lepoutre, F. Bastien, University of Reims ChampagneArdenne / UMRI SEBIO; I. Bonnard, Université de Reims Champagne Ardenne / INERIS URCA ULH SEBIO; J.P. Dubey, United States Department of Agriculture / Animal Parasitic Diseases Laboratory; I. Villena, D. Aubert, Laboratoire de Parasitologie-Mycologie / EA; O. Geffard, Irstea / UR MALY Laboratoire Ecotoxicologie; A. Geffard, Université de Reims Champagne Ardenne

The protozoa *Toxoplasma gondii* and *Cryptosporidium parvum* are public health priorities since their oocyst form is exceptionally resistant to environment insults and can remain infectious for months or years. They are present in various watercourses as recreational, surface, drinking, river and seawater. *Cryptosporidium* oocysts were reported in a range of bivalve mollusc species but until now there is no information whether freshwater crustacea are able to accumulate protozoan oocysts. The amphipod species *Gammarus fossarum* selected in this study is widespread and common in rivers and streams of Western Europe. *G. fossarum* have an important ecological role in the trophic chain since they represent a reserve of food for macroinvertebrate, fish, bird and amphibian species. The purpose of the present study was to determine whether *Gammarus fossarum* could accumulate in their tissue *T. gondii* and *C. parvum* oocysts after experimental exposure and potential use of *Gammarus fossarum* as matrix for biomonitoring of protozoa concentration in freshwater systems. *Gammarus fossarum* were exposed to 200; 2,000 and 20,000 oocysts per gammarid and per day during 21 days followed by 5 days of depuration. DNA detection of *T. gondii* and *C. parvum* oocysts was carried out using TaqMan real-time PCR. *C. parvum* DNA was detected in gammarids in only one out of four pools for the higher concentration and after 14-day exposure. However, concerning *T. gondii*, DNA was detected after 7-days exposure with the two highest concentrations, and from 14-day exposure *T. gondii* DNA was highlighted in gammarids for all conditions. Between 0 and 14-day, oocyst number detected increased with the exposure time, then a saturation effect was observed between 14 and 21-day for the two highest concentrations. A significant dose-response relationship was observed and the maximum quantity of oocysts detected in gammarid tissues is obtained after exposure to 20,000 oocysts per organism and per day. After 5 days of depuration, *T. gondii* oocysts were still present in gammarids indicating the integrative nature of *G. fossarum*. These results show for the first time that a freshwater crustacean is able to bioaccumulate *T. gondii* oocysts suggesting that *Gammarus fossarum* is a potential effective bioindicator of protozoan contamination in biomonitoring studies. Moreover, due to their important position in freshwater food webs, *G. fossarum* could also play a role in the trophic transfer of protozoa

TH086

Snail watch to survey the transfer of PCB and PCDD/F on a polluted site converted into a photovoltaic power plant

B. Pauget, University of Franche-Comte, UMR UFC/CNRS 6249; O. Faure,

University of Lyon / UMR CNRS EVS EMSE Géosciences et Environnement; K. Perronnet, INERIS / Direction des Risques ChroniquesUnité Impact Sanitaire et Expositions; A. de Vaufleury, University of Franche-Comte / Department of ChronoEnvironment

In 2008, a fire on a former industrial site in Saint Cyprien (France) caused a severe contamination with persistent organic pollutants (POP) to surrounding soils. About 14 hectares of pasture were consequently forbidden to agricultural use. To give a new usage to this site, a power plant was built in 2010 by Luxel SAS. This installation produces green electricity since early October 2013 and constitutes a pilot site for research on POP toxicity and degradation processes over time with bioindicators. The objective of the research program TROPE (Transfer and Risk of Organic PErsistent pollutants for snails) was to assess, thanks to active biomonitoring, the bioavailability of PCBi, PCB-DL and PCDD/F to a soil invertebrate living at the soil surface, the ubiquitous land snail, *Cantareus aspersus*. Snails were caged for 28 days on 4 grassy plots with increasing POP contamination (3631 to 34942 ng.kg^{-1} dw for ?7 PCBi, 2 to 222 ng TEQ$_{OMS2005}$.kg^{-1} dw for ?17 PCDD/F and 1.15 to 22.8 ng TEQ$_{OMS2005}$.kg^{-1} dw for ?12 PCB-DL. An additional plot highly contaminated (>400 mg.kg^{-1} PCBi and sum PCDD/F + PCB-DL > 20,000 ng TEQ.kg^{-1}) located near the studied site was also studied. Internal residues in the soft body of snails for the sum of the ?7 PCBi were from 556 to 462,124 ng.kg^{-1} fw whereas the ?17 congeners of PCDD/F varied from 0.052 to 1.18 ng TEQ .kg^{-1} and for the ?12 PCB-DL from 0.064 to 72 ngTEQ.kg^{-1}. The ratio PCDD/F / PCB-DL was from 1 to 2.6 and the ratio PCBi/PCB-DL from 4252 to 8689. Among the PCBi, congeners 101, 138 and 153 were the most accumulated pollutants. For PCB-DL, PCB105 and 118 were the most abundant whereas for the PCDD, OCDD and HpCDD were predominant in the snail tissues. Results showed that POP are bioavailable for snails and may reach high internal body concentration in highly contaminated plots. This study provides first data on the capability of land snails to accumulate various PCB, PCB-DL and PCDD/F and reveals that these soil invertebrates may be a source of POP exposure to their consumers. Two other campaigns of biomonitoring are planned in the coming years to assess the evolution of bioavailability of POP on this polluted area, unsuitable for agricultural purposes, but that has recovered an industrial value. These studies will help to sharpen our understanding of the PCB impact on the ecosystems.

TH087

Evaluation of an endocrine disruptor (Vinclozolin) in the benthic organism Chironomus riparius (Diptera)

M. Aquilino, UNED; P. Sanchez-Arguello, INIA - National Institute for Agricultural and Food Research and Technology / Environment; J. Martinez-Guitarte, UNED / Fisica Matematica y de Fluidos

The dicarboxiamide Vinclozolin (Vz) is a widely used fungicide for agricultural purposes. Because of this, it is found as a residue in the environment, detected in underground water, lakes, rivers, and seawater. Most of the toxicity studies have been focused on vertebrates showing antiandrogenic activity, however, few studies have investigated their effects on invertebrates, which are key organisms in aquatic ecosystem maintaining. In this work we have analyzed the effects caused by Vz on fourth instar larvaeof *Chironomus riparius*, a dipteran used frequently as reference species in ecotoxicology. Alterations that exposure of the larvae for 24 and 48 hours causes on several genes related with the endocrine system and the detoxification pathways of this insect were evaluated using Real-Time PCR. Two of them, *Disembodied* and *Cyp18a1*, are related with the metabolism of ecdysone, one of the main hormones of insects involved on development. *Membrane Associated Progresterone Receptor*, the coding gene for an orphan receptor, and *Forkhead Box O*, a gene which produces a protein involved in the insulin response pathway, were also analyzed. On the other hand, *Cyp450G* and *GSTd3* transcriptional activity was studied to analyze if they are involved in the detoxification process of Vz. The results show a significant alteration of transcription activity of some of these genes indicating that the presence of Vz affects the cell processes in this organism. The results obtained show the ability of Vz to up-regulate hormonal related genes in *C. riparius* larvae after exposures and establish the first evidence of its endocrine disruptive effects in insects. This work was supported by the Plan Nacional de Investigación Científica, Desarrollo e Innovación Tecnológica (Spain), grant CTM2012-337547 from the Ciencias y Tecnologías Medioambientales program. M.A. is the receiver of a predoctoral contract Ministry of Economy and Finance (BES-2013-064041).

TH088

Formaldehyde Chemical Substance Flow Analysis in South Korea

Y. Hwang, J. Park, Inha University; J. Kim, University of Technology of Troyes / Department of Humanities Environment Information Technology CREIDD; J. Moon, Inha University

A chemical substance is any material that has a definite chemical composition (Hill et al. 2005). Currently chemical substances and materials are widely used in all kind of industry and household, almost everywhere and in everything. On the other hand, these chemical substances and materials have important issues such as risk related with hazardous and toxic in their life cycle from manufacturing and use to the end of life. Also historically, many chemical accidents and industrial disasters were occurred in the world. Up to date, therefore, related regulation and assessment tools (e.g., Regulation on Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH), risk assessment, health effect of chemical exposure) are widely applied for chemical substances and materials. There have been some studies on the guiding principles of chemical accident prevention, preparedness and response. However, the study on chemical substance flow analysis in country level and its application was not well conducted. In this study, therefore, formaldehyde (CH_2O), which is used mainly to produce resins used in particleboard products and as an intermediate in the synthesis of other chemicals was selected. Formaldehyde is used predominantly as a chemical intermediate. It also has minor uses in agriculture, as an analytical reagent, in concrete and plaster additives, cosmetics, disinfectants, fumigants, photography, and wood preservation (US EPA, 1988). The purpose of this study is quantifying, analysing and mapping of the formaldehyde substance flows by using material flow analysis (MFA) method in South Korea. Our result shows that the number, location of manufactures using formaldehyde as well as formaldehyde's flow (import, export, stocks and flows) in Korean industrial system (between industries including companies). Finally the result of this study can support for chemical accident prevention system and sustainable chemical management in South Korea.

TH089

Biological effects of different pesticides and their mixtures on Eisenia andrei: laboratory experiments and field studies using caged earthworms

S. Sforzini, C. Oliveri, A. Viarengo, University of Piemonte Orientale / Department of Sciences and Technological Innovation DiSIT

Pesticides are harmful to specific target organisms; however, selectivity is never absolute and therefore pesticides represent a risk also to non-target organisms. Most of the studies using model organisms in ecotoxicology have focused on the evaluation of high-level endpoints (i.e. mortality and reproduction) that provide information about possible effects at organism/population level; data concerning sublethal effects have been rarely described. In this study we evaluated the toxicity of different pesticides widely used in agriculture on the earthworm *Eisenia andrei* by simulating in the laboratory the processes carried out in the rice- and vine-fields. For this purpose, a set of biomarkers able to highlight the alterations of the health status of the organisms from the most sensitive molecular changes to whole-organism responses was employed. The results demonstrated that all the studied compounds at concentrations recommended by the manufacturers did not affect the worm survival but provoked relevant stress and genotoxic effects on 28 d exposed animals. To verify the results of this laboratory study, we also realized field studies. To this end, a method was developed to maintain the earthworms in field for 10/28 d. The animals caged in the sites of rice (during the dry period) and vine cultivation treated with the pesticides (at the doses used in laboratory experiments) survived. However, also in these animals, significant effects on sublethal endpoints (such as lysosomal membrane stability, Ca^{+2}-ATPase activity and mitochondrial functionality) were observed. In both crops, the results highlighted genotoxic effects as demonstrated by the increase of the level of the DNA damage and of the micronuclei frequency.

TH090

Application of bioassays with Enchytraeus crypticus to evaluate the effect of biochar in metal bioavailability

D. Gomez, Leitat Technological Center; V. Gonzalez, Safety and Sustainability; M. González-Alcaraz, Faculty of Earth and Life Sciences, VU University / Ecological Science; K. van Gestel, VU University Amsterdam / Ecological Science; M. Diez-Ortiz, Leitat Technological Center

Mining activity results in the accumulation of waste scattered in the landscape. When contaminants contained in these wastes are mobilized, the risk of pollution of surrounding areas increases, degrading soil quality and causing serious problems to human health. The main objective of MINETOX project is to study the effect of biochar in metal availability of different mine wastes over time by means of the physicochemical and ecotoxicological characterization of the treatments. In this study, two mine wastes (acid and basic) were amended with two different types of biochar (one from pruning remains and other from sewage sludge) separately, in order to study their effect on metal bioavailability and to modify their potential environmental impacts. Since the application of the amendment was expected to result in metal immobilization in soils, the efficiency was tested both in mine wastes and mine waste pore waters. Mine wastes were amended with 6% of biochar, and pore waters were extracted at the beginning and the end (after 6 months of incubation) of the experiments for all treated and untreated wastes. Accumulation and toxicity of treated and untreated wastes in the potworm *Enchytraeus crypticus* were investigated in mine waste pore water solution embedded in an inert quartz sand matrix. Additionally, treated and untreated wastes were mixed with uncontaminated Lufa 2.2 reference natural soil to obtain waste concentration of 100, 50, 25, 12.5, 6.25 and 3.13% (w/w), and survival and reproduction was observed in all treatment at each dilution concentration. Preliminary results show than organisms were more affected when exposed to mine wastes than when exposed to the pore water solutions. The latter could indicate that when exposed to mine wastes the organisms could be still affected by the fraction of metals immobilized in the mine wastes. Toxicity seems to decrease when biochar was added to mine waste but differences between two types of biochar were not significant. In this study, we evaluate the efficiency of different amendments from a double perspective, taking into account the two different exposure pathways (via pore water and via soil ingestion).

TH091

Stratification of soil arthropods in top soil layers

S.B. Dehelean, Mitox Trial Management BV; E.d. Bree, Eurofins-Mitox; F.M. Bakker, Mitox Consultants

The persistence of pesticides in soil is well studied. Their distribution depends on their physical and chemical properties together with the soil characteristics. Studies have shown that traces of pesticides can be found in soil up to several years and down to depths over two meters. Little is known on the stratification of the soil arthropods in the top soil layers and even less about the effects of pesticides on them. Therefore, our overall aim is to study these communities and their response to pesticide exposure. An ongoing pilot study, started in May 2015, aims to identify the arthropods groups found in the top 40 cm of soil and record their seasonal activity. Soil arthropods were sampled with a tubular trap ("slide trap") specifically designed for this aim, at four depths: 0-10 cm, 10-20 cm, 20-30 cm and 30-40 cm. Each tube has approximatively 70 holes of 5 mm diameter evenly distributed at the target depth for a maximized stratified sampling. To collect the arthropods a funnel and a jar, filled with 50 ml of ethyl-glycol, were attached at the bottom of the tubes. The traps were setup in May 2015 and are checked every two weeks. Results of the first six months show that adult beetles and their larvae can be found up to 40 cm depth, and their vertical migration appears to be influenced by the environmental conditions. Species of Diplura are mainly found at 20-30 cm depth. Individuals of the subphylum Myriapoda have a split stratification, with high numbers in the layers of 0-10 cm and 20-30 cm. Remarkably species of Pauropoda and Pseudoscorpions show up frequently in layers deeper than 20 cm. Full taxonomic list for all groups and a detailed model of the slide traps used will be presented with the poster. Presently studies are designed to look at the arthropods communities in the first 10 cm and might overlook the effects of pesticides on taxa such as Diplura and Myriapoda, groups that are more abundant in deeper layers. Our study will bring valuable information on how these communities respond to pesticides in deeper layers missed in previous in situ studies. Also it will show if and how the environmental conditions influence the response.

Using in situ assays with two freshwater producers to assess effects of wildfires on aquatic systems

M.S. Oliveira, Biology; A. Ré, Aveiro University & CESAM / Biology; J. Puga, I. Campos, University of Aveiro / Department of Environment Centre for Environmental and Marine Studies CESAM; J.L. Pereira, F. Gonçalves, University of Aveiro / Department of Biology Centre for Environmental and Marine Studies CESAM; J.J. Keizer, University of Aveiro / Department of Environment and Planning CESAM; N. Abrantes, University of Aveiro / CESAMDAO

Portugal is the European country where forest fires devastate more area, with an average of 144 000 ha per year in the last decade, and a tendency to increase both in frequency and area. Wildfires constitute a concerning environmental problem once they have adverse and diversified effects impacts in the terrestrial, atmospheric and aquatic compartments. It is known that wildfires affect aquatic systems by altering its physical and chemical proprieties through the input of pyrolytic substances, such as polycyclic aromatic hydrocarbons (PAHs), and metals associated to ash/soil loads from the surrounding burnt areas. The majority of the available studies regarding the effects of wildfires on aquatic biota have been performed by using laboratory single species bioassays. Once *in situ* exposition enable to assess more realistic environmental multi-stress conditions and their fluctuations, in situ assays using two aquatic producers' species –the microalgae *Raphidocelis subcapitata* and the macrophyta *Lemna minor* - were performed. A recently burnt area was selected near Miranda do Corvo (Portugal) and five sites were selected to conduct the assays: two in the main water course of the watershed - Ceira river, being one located upstream (RUS) and the other downstream (RDS) the burnt area; two in tributary streams within the burnt area (SUS and SDS); and one in a stream located in an adjacent non-burnt area (CS). The assays took place at the time of the first major rainfall events and lasted for 13 days. Personalized test chambers were elaborated, allowing floatage and luminosity entrance for both tested species. *R. subcapitata* was immobilized in alginate beads while *L. minor* leaf colonies were tested freeform. The cellular concentration of microalgae in beads and the initial number of fronds and weight for *L. minor* were determined in the beginning and in the end of the assay, allowing to calculate the growth rate. The present results showed an inhibition in the growth rates of both species when exposed to the most impacted sites (RDS, SUS and SDS) comparatively to the reference sites (RUS and CS) . Hence, the *in situ* bioassays revealed to be effective to discern toxic effects on aquatic primary producers due to diffuse contamination from wildfires.

TH093

Off-site environmental impacts of wildfires: Assessment of the toxicity of post-fire runoff on freshwater aquatic species

I. Campos, University of Aveiro / Department of Environment Centre for Environmental and Marine Studies CESAM; J.J. Keizer, University of Aveiro / Department of Environment and Planning CESAM; V. Silva, University of Aveiro / CESAM Departmenf of Environment; P. Pereira, University of Aveiro / CESAM Department of Biology; N. Abrantes, University of Aveiro / CESAMDAO

Wildfire is a major disturbance of forests worldwide, posing an important threat to life, human goods and natural resources. Interestingly, wildfires have an important role in contaminants production and mobilization, such as polycyclic aromatic hydrocarbons (PAHs) and trace elements. For instance, these contaminants could be mobilized during a wildfire from ashes and sediments loads and may eventually reach the nearby aquatic systems by surface runoff. In this regard, wildfires represent a relevant diffuse source of PAHs and trace elements to aquatic systems that has, so far, been poorly investigated, in particular, their potential toxicity on aquatic biota. The current study aims to mitigate such lack of knowledge for PAHs and trace elements, a well-recognized persistent toxicants with potential harmful impacts on the environment and on human health. To address the potential ecotoxicological effects posed by such compounds and their mixtures, the present work was focused on their effects in the following aquatic species: bacteria (*Vibrio fischeri*), the algae (*Raphidocelis subcapitata*), the macrophyte (*Lemna minor*) and the invertebrate (*Daphnia magna*). These species were exposed to different dilutions (12.5, 25, 50, 75 and 100%) of post-fire runoff and surface water from the burnt catchment outlet. All the samples were collected during the first rainfall events after the wildfire. The concentration of the fifteen PAHs identified by USEPA as priority contaminants were analysed by gas chromatography-mass spectrometry (GC-MS) and the trace elements (V, Mn, Co, Ni, Cu, As, Cd and Pb) by inductively coupled plasma-mass spectrometry (ICP-MS). The endpoints tested in the ecotoxicological assays were: luminescence inhibition for the *V. fischeri*, growth inhibition for the *R. subcapitata* and the *L. minor*, and immobilization for the *D. magna*. Lethal and sub-lethal dose response curves were determined as well as the corresponding endpoints (NOEC, LOEC, EC_{50} and EC_{20}). The preliminary results allowed to discriminate the off-site effects of wildfires on distinct aquatic species. Moreover, it allowed to determinate the threshold concentrations of PAHs and trace elements that can be considered at low/high risk for aquatic biota and therefore, the aquatic systems. This information is of crucial importance to predict the risks and effects of the surface water pollution by recently burnt areas and the propagation of toxic effects from the lower to the upper trophic levels.

TH094

Biofuels and their aquatic toxicity - Biotesting 3-methyltetrahydrofuran

J. Brendt; S. Heger, Institute for Environmental Research, RWTH / Institute for Environmental Research; K. Bluhm, Instit.for Environm.Research, RWTH Aachen Univ. / Department of Ecosystem Analysis; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis

The rapidly growing industrial sectors in many developing countries, such as China or India, require an increasing volume of fuel for the transport sector. In parallel, environmental concerns regarding petroleum based fuels and the request for independency on oil result in a growing demand for renewable energy sources such as biofuels. However, a release into the environment increases with a rise in biofuel production and consumption. Therefore, a comprehensive assessment of the environmental hazard potential is aggravated by the lack of ecotoxicological data. Ecotoxicological bioassays can be used for the detection of potential hazards for aquatic ecosystems at a very early stage of the development. This study is focused on the ecotoxicological investigation of the potential biofuel 3-methyltetrahydrofuran (3-MTHF) in aquatic systems. To evaluate the hazard potential of this new potential biofuel for the environment 3-MTHF has to be tested in different aquatic testsystems monitoring different levels of organisation, such as acute toxicity and embryo toxicity using the fish embryo toxicity (FET) test with *Danio rerio* (OECD 236), the acute immobilization assay with *Daphnia magna* (OECD 202) and algae growth inhibition test with *Desmodesmus subspicatus* (OECD 201). Additionally an *in vitro* micronucleus-test with Chinese hamster V79 cells (ISO 21427-2) was performed to investigate the genotoxic potential of the fuel candidate. Differences in toxic potencies of 3-MTHF compared to other fuel candidates can be used to identify the least toxic biofuels and focus further research on these candidates. An early investigation of biofuels can decrease the risk for the environment and, thus, reduce the potential of these new fuels to become a source of contamination for aquatic systems.

Acknowledgement: This work was performed as part of the Research Cluster "Tailor-made fuels from biomass", which is funded by the Excellence Initiative by the German federal and state governments to promote science and research at German universities.

TH095

Occurrence of four potentially SVHC-classified semipolar PAHs in selected environmental matrices and their ecotoxicological impacts

C. Polleichtner, German Environment Agency (UBA) / Ecotoxicological Laboratory; A. Behnke, Biochemical Institute for Environmental Carcinogens, Germany; D. Einhenkel-Arle, German Environment Agency; S. Jessel, A. John, Biochemical Institute for Environmental Carcinogens, Germany; C. Kussatz, M.

Lukas, German Environment Agency; A. Seidel, Biochemical Institute for Environmental Carcinogens, German

Semipolar polycyclic aromatic hydrocarbons (heterocyclic PAHs or PANHs, PASHs and PAOHs) are often found in UVCBs (chemical substances of unknown or variable composition, complex reaction products and biological materials) from coal and crude mineral oil and derived products in association with homocyclic PAHs (Schwarz et al., 2014). In spite of the fact that there are some indications of toxic properties comparable to their homocyclic analogues, the toxicological characterization of semipolar PAHs is often still insufficient. Identification and characterization of substances of very high concern (SVHC) is one of the key components of the REACH (registration, evaluation, authorization and restriction of chemicals) Regulation of the European Union. Annex XIII of the REACH Regulation defines the properties of SVHC. Substances with persistent, bioaccumulative and toxic properties (PBT) are of very high concern for the environment and can be regulated by authorities. Within a joint research project the German Environment Agency (UBA) and the Biochemical Institute for Environmental Carcinogens (BIU) investigated the ecotoxicological properties of four semipolar PAHs potentially identified as SVHCs: - Benzo[*b*]naphtho[2,1-*d*]thiophene - Dibenz[*a,j*]acridine - Benzo[*b*]naphtho[1,2-*d*]furan - 7*H*-Dibenzo[*c,g*]carbazole The ecotoxicological investigations were carried out at the UBA's ecotoxicological laboratory in accordance to OECD test guidelines using aquatic organisms from different trophic levels: green algae (*Desmodesmus subspicatus*), crustaceans (*Daphnia magna*) and fish embryo (*Danio rerio*). At the BIU semipolar PAHs were prepared in high purity and water solubility of each compound was determined in the used test media and at the relevant test temperatures. The results obtained for the PAH's ecotoxicological potential on the three investigated aquatic species are presented. In addition, PAH levels found in blue mussels (*Mytilus edulis* L.) collected at several locations along the German coastline as well as PAH levels found in fresh kale (*Brassica oleracea* var. *sabellica* L.) and certified harbour sediment (BCR-535) are reported. (2014) Semipolar polycyclic aromatic compounds: Identification of 15 priority substances and the need for regulatory steps under REACH regulation. Integr. Environ. Assess. Manag. 10: 415-428.

TH096

Oral Bioavailability Study of PAHs in Coal Tar/Coal Tar Pitch Clay Pigeon Target Fragments from Range Sites

B.H. Magee, ARCADIS; N.D. Forsberg, G.C. Hoeger, ARCADIS / IEST

An *in vivo* oral bioavailability study was performed to determine the relative bioavailability of PAHs in clay pigeon target fragments at military range sites. These fragments, which are mixed with native soil, are composed of PAHs in a site-aged coal tar/coal tar pitch and limestone matrix. It was expected that the fragment matrix would reduce the oral bioavailability of PAHs compared to that seen in animal studies using pure benzo(a)pyrene in solvents. To test this hypothesis, an oral bioavailability study was performed with female B6C3F1 mice (8 mice per dose group) fed soils or soil extracts at a rate of 5% in the diet for fourteen days. Four test soils contained 0.5, 4.5, 28 or 183 mg/kg benzo(a)pyrene (BaP). BaP concentrations in diets were 0.04, 0.39, 2.55, and 19.17 mg/kg. A high resolution mass spectrometry method was developed to detect low levels of the following PAH metabolites in mouse urine: 3-hydroxy-benzo(a)pyrene, 9-hydroxy-benzo(a)pyrene, 3-hydroxy-benz(a)anthracene, and 3-hydroxy-chrysene. The fractions of total dose excreted in the urine were compared for the soil and the soil extract groups to derive Relative Bioavailability Factors (RBAFs) for use in risk assessment. The RBAFs were 0.20 for BaP, 0.23 for benz(a)anthracene, and 0.28 for chrysene.

TH097

Dermal Absorption Study of PAHs in Coal Tar/Coal Tar Pitch Clay Pigeon Target Fragments from Range Sites

B.H. Magee, ARCADIS; N.D. Forsberg, G.C. Hoeger, ARCADIS / IEST

An *in vitro* dermal absorption study with human skin was performed to determine the dermal absorption of PAHs in clay pigeon target fragments at military range sites. These fragments, which are mixed with native soil, are composed of PAHs in a site-aged coal tar/coal tar pitch and limestone matrix. It was expected that the matrix would reduce the dermal absorption of PAHs compared to that seen in animal studies using pure benzo(a)pyrene (BaP) in solvents. For human health risk assessment, USEPA assumes that 13% of administered PAHs are absorbed based on an *in vivo* study in rhesus monkeys by Wester et al. (1990). This study evaluated dermal absorption by spiking *unaged* soil samples with ^{14}C-BaP and testing the spiked soil immediately. Several published studies showed that aged, weathered PAHs have lower dermal absorption compared to freshly spiked soil samples. To test this hypothesis, an *in vitro* study was performed in Franz diffusion cells with split-thickness fresh-frozen human skin samples from male and female donors aged 23-65 years. Test articles were applied to skin for 24 hours, then washed off. Collection of receptor fluid samples continued for a total monitoring period of 72 hours. Skin samples were stripped five times with tape to remove the stratum corneum and any remaining surface soil. PAHs were analyzed in the dermis and in the surfactant-containing receptor fluid by high performance liquid chromatography with fluorescence detection to a detection limit of 100 ng/mL to define absorbed dose. Test articles included three site soils with BaP concentrations of 8, 51 and 383 ppm. Dermal absorption of BaP and six potentially carcinogenic PAHs was less than 1%. A freshly spiked control sample gave 9% absorption for BaP.

TH098

Ecological Risk Assessment of Polycyclic Aromatic Hydrocarbons in Water, Sediment and Dominant Fish from Designated Zones of the Lagos Lagoon, Nigeria

T.O. Sogbanmu, A.A. Otitoloju, UNIVERSITY OF LAGOS / Zoology

The ecological risk assessment (ERA) of priority pollutants such as Polycyclic Aromatic Hydrocarbons (PAHs) are imperative due to their cascading biological effects along the food chain in the aquatic environment. In this study, the levels and ecological risk assessment of sixteen (16) priority PAHs were evaluated in water, sediment and dominant fish species sampled from designated anthropogenic-impacted zones (Ilaje, Iddo, Atlas cove and Apapa) of the Lagos lagoon in the wet and dry seasons from 2012 to 2014. PAHs in the samples were analyzed using GC/FID. Indices such as Effects Range Low/Effect Range medium (ERL/ERM), Threshold / Probable Effects Level (TEL/PEL), sediment and fish pollution classification based on sum PAHs and Bioconcentration Factor (BCF) were utilized for the ERA. The results showed that the dominant fish species were *Sarotherodon melanotheron* (Black-Chinned Tilapia), *Gerres melanopterus* (Gerres), *Liza falcipinnis* (Sickle-fin Mullet) and *Pseudolithus elongatus* (Bobo Croaker) at the Ilaje, Iddo, Atlas cove and Apapa zones respectively. The average sum 16 PAHs (∑PAHs) and range were 515.58µg/L (194.94 (Ilaje, wet season) - 1006.49μg/L (Apapa, wet season)), 739.45μg/kg (301.81 (Ilaje, wet season) - 1290.16μg/kg (Apapa, wet season)) and 19.78μg/kg (8.80 (*S. melanotheron*, dry season) - 26.10μg/kg (*G. melanopterus*, dry season)) in water, sediment and fish respectively. Naphthalene was dominant in water and sediment samples while phenanthrene, anthracene, fluoranthene and pyrene were predominant in the fish species across the zones and seasons. ERA of PAHs in the sediments showed that biological effects will occur frequently at the Apapa zone and occasionally at all other zones based on the levels of naphthalene, acenapthylene, acenaphthene, fluorene and benzo(a)anthracene in both seasons. Apapa zone was highly polluted while other zones were moderately polluted in both seasons based on ∑PAHs in the sediments. Fish species from all the zones were minimally contaminated in both seasons except *S. melanotheron* based on ∑PAHs in fish. BCF results showed that PAHs did not bioconcentrate in the fish species except for pyrene with a BCF value of 2.28 in *G. melanopterus*. The study recommends that the specific PAHs identified as ecological risk factors in the Lagos lagoon sediments should form a basis for the establishment of environmental quality standards for PAHs in Nigerian coastal waters as well as their inclusion in ecomonitoring programmes.

TH099

Water quality assessment of five cascading reservoirs of Iguaçu River through multi-biomarker approach in fish

F. Yamamoto, M.V. Pereira, E. Lottermann, Universidade Federal do Paraná / Cell Biology; G. Santos, Universidade Federal do Paraná / Department of Genetics; T. Stremel, Universidade estadual de ponta grossa UEPG; H.B. Doria, Universidade Federal do Paraná / Cell Biology; P. Gusso-Choueri, Unesp / Chemistry; S.X. Campos, UEPG; C.F. Ortolani-Machado, Universidade Federal do Paraná / Cell Biology; M. Cestari, UFPR / Genética; F. Filipak Neto, Universidade Federal do Paraná / Cell Biology; C.d. Oliveira Ribeiro, Universidade Federal do Paraná / Department of Cellular Biology

The Iguaçu River, located at southern region of Brazil, has great socioeconomic and environmental importance due to its high endemic fish fauna as well as its ability to generate hydroelectric power and the potential to supply water for human use. To date, no previous study has reported an integrated evaluation of chemical analysis and biological responses in Iguaçu River, which is considered ideal for a better environmental risk assessment. The local environmental agency describes water quality improvement along the river course, since there is intense discharge of pollutants in the river's source. For the current study, three different Brazilian fish species (*Astyanax bifasciatus, Chrenicicla iguassuensis* and *Geophagus brasiliensis*) were captured for a multi-biomarkers approach analysis in five cascading reservoirs of Iguaçu River. Chemical analysis in water, sediment and muscle indicated high levels of metals in all reservoirs. Chromium (Cr) levels in water were detected above the permitted concentrations set by governmental agencies. High levels of polycyclic aromatic hydrocarbons (PAHs) were also detected in fish's bile for the three different species analyzed. An ELISA kit produced for the native species *Geophagus brasiliensis* detected vitellogenin expression in male fish from the five reservoirs. Integration of the data through FA/PCA analysis demonstrated the poorest environmental quality of the reservoir farthest from river's source, which is the opposite of what is reported by the environmental agency. The high levels of metals and PAHs in the five reservoirs of Iguaçu River associated with the biological responses of fish show the impacts by anthropic activities to this area and not confirm a gradient of pollution from the source toward Iguaçu River's mouth.

TH100

Sediment quality assessment in Ho Chi Minh City canals.

T.L. Bui, Institute for Environment and Resources , Vietnam National University Ho Chi Minh City / Environmental Toxicology; D. Lan Chi, Institute for Environment and Resources, Vietnam National University Ho Chi Minh City / Ecotoxicology; T. Combi, Interdepartmental Centre for Environmental Science Research, University of Bologna; P. Lara-Martin, Universidad de Cádiz Spain / Physical Chemistry; M. Casado-Martinez, Centre Ecotox; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology

Ho Chi Minh City metropolitan region is the largest urban and industrial hub of South Vietnam, with more than 6 million inhabitants and a large number of big factories and artisanal plants. Located in the Mekong delta, the area is characterized by a complex system of canals that play a vital role for the region and its inhabitants. They act as reservoirs for water run-off and drainage and they are used for transportation and as a source for natural resources. Due to public health concerns an important sanitation program has been undertaken in the last decade for the reduction of wastewater pollution and flooding. At present, the main canals are recovering after clean-up and clean waters have attracted fish again, with increasing stocks thanks to repopulation initiatives. In 2015 we carried out a pilot study to assess the quality of recent sediments from Ho Chi Minh City canals. Surface sediments were collected from 6 canals, 4 of them located in the metropolitan area and 2 from suburban areas. Sediments were subject to physico-chemical and ecotoxicological characterisation, the physico-chemical characterisation consisting of the quantification of trace metals and organic micropollutants and the ecotoxicological assessment through the use of existing chemical quality guidelines and standard sediment toxicity tests. The results show that the sediments from the canals from both the metropolitan and suburban areas accumulate a mixture of contaminants with concentrations of several PAHs and PCBs above the corresponding thresholds for effects to benthic organisms. Several pesticides were quantified in the sediments but the highest concentrations were measured for permethrin in the case of the sediments from the metropolitan area and for bifenthrin in sediments from suburban areas (3692.9 ng/g dw and 477.6 ng/g dw, respectively). Conspicuous concentrations at the μg/g order were found for the fragrances galaxolide and OTNE whereas nonylphenol, triclosan and the UV filters octocrylene, 2-EHDP and EHMC were measured at all canals at concentrations of several tens and even hundreds ng/g. The results of the chemical analyses are corroborated by the different levels of toxicity to crustaceans although no or slight toxicity was observed to rooted macrophytes in laboratory toxicity tests.

TH101

The Impact of Surrounding Land Use and Site History on Metal Concentrations and Bioaccessibility in Canadian Urban Parks

M. Dodd, Royal Roads University / School of Environment Sustainability; A. Durojaiye, J. Ehizojie, Royal Roads University; K. Allan, SLR Consulting (Canada) Ltd.

To assess the potential risk associated with exposure to metal contaminants in Canadian urban green spaces, surface soil samples taken from exposed areas with high potential for human soil contact at various parks and playgrounds were analyzed for total metals, pH, TOC and metal bioaccessibility. The green spaces were selected from Halifax (10), Saint John (11), Fredericton (11), Ottawa (8), Toronto (17), Montreal (20), Regina (8), Winnipeg (8), Edmonton (17) and Victoria (22). Arsenic, Cr, Cu, Pb or Zn concentrations in 19 out of the 134 soil samples analyzed exceeded the Canadian Council of Ministers of the Environment (CCME) soil quality guideline for residential/parkland use. Apart from the influence of naturally occurring bedrock on As, soil metal concentrations were influenced by the proximity of the parks to industrial activities (e.g., metal recycling), heavy traffic corridors and former contaminated sites. Arsenic concentrations were particularly elevated in Halifax , Saint John and Fredericton. The elevated concentrations in these three cities reflected natural geological processes since some areas in the provinces these cities occur have high natural As concentrations that exceed human health risk-based guidelines due to bedrock and natural soil enrichment. The highest Pb concentrations (were detected in parks located near heavy traffic corridors while elevated Cu, Cr and Zn levels were associated with parks situated either on former industrial sites or near current metal related industrial sites. The mean metal bioaccessibility were As (24%), Cd (80%), Cu (39%), Pb (61%), Ni (17%) and Zn (32%). Based on the total metal concentrations, soil properties and bioaccessibility data the risk associated with exposure to metals in soils in most of the urban parks studied were deemed fairly low except Pb.

TH102

In vivo and in situ methods for assessment of the implication from a municipal wastewater treatment plant for the receiving stream

S.K. Könemann, Institute for Environmental Research; Y. Mueller, S. Hotz, RWTH Aachen University / Department of Ecosystem Analysis ESA; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis; S. Schiwy, Institute of Environmental Research-RWTH Aachen / Department of Ecosystem Analysis ESA

Micropollutants, like pharmaceutical residues, in municipal wastewater are not sufficiently removed by secondary and tertiary treatment methods in wastewater treatment plants (WWTPs). As a consequence, complex mixtures of micropollutants discharge into the receiving streams and may cause various effects on aquatic biota, like fish and macroinvertebrates. To decrease, or even fully prevent the release of micropollutants into the environment qarternary treatment methods, like ozonation, are currently tested in several WWTPs in Switzerland and Germany. In the course of the DemO_3-Project, a full-scale ozonation is planned to be built at the WWTP Soers in Aachen, Germany. A crucial part of this project is the evaluation of the ecological and chemical state of the receiving stream, the River Wurm. To be able to determine the impact of the ozonation on the state of the stream, the evaluation is conducted before and after the implementation.The present study focused on the status quo of the River Wurm and aimed to determine the ecotoxicological implication from WWTP Soers for the river. In order to assess occuring effects, water samples were taken after three treatment steps at the WWTP and at three sampling sites along the river: upstream of the rain spillway basin, downstream of the rain spillway basin and downstream (approx. 2 km) of the WWTP. These samples were tested as both native samples and extracts on embryos of *Danio rerio* (FET). Further, an*in situ*bioassay on feeding rate inhibition with encaged *Gammarus pulex* was conducted for 7 days. The gammarids were exposed at the mentioned sampling sites in the river and an additional site immediately after the outlet of the WWTP.The first results of the FET show no impairment at all for the river samples, whereas, as expected, the embryos were heavily affected by the WWTP samples. The highest ecotoxicological potential was found in the inlet, where a 100 % mortality was found in the two highest concentrations, followed by a high number of sublethal effects in the lower concentrations. The first results of the feeding rate inhibition test indicate a decrease of ca. 30 % in feeding rate downstream of the rain spill basin, while the highest feeding rate was found 2 km downstream the WWTP. The lowest feeding rate or the highest inhibition is expected to be found immediately after the WWTP outlet. To support and strengthen these first findings, further tests are needed.

TH103

Mechanism-specific evaluation of a waste water treatment plant and its downstream river Wurm

Y. Mueller, RWTH Aachen University / Department of Ecosystem Analysis ESA; S.K. Könemann, Institute for Environmental Research; S. Hotz, RWTH Aachen University / Department of Ecosystem Analysis ESA; S. Schiwy, Institute of Environmental Research-RWTH Aachen / Department of Ecosystem Analysis ESA; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis

The European Water Framework Directive aims to achieve a good chemical and biological state of all surface waters until 2015. However, the good biological state is only reached by around 20 % of the German surface water bodies. One reason might be the release of a variety of anthropogenic contaminants by waste water treatment plants (WWTPs). It could occur that these substances are not sufficiently eliminated via the conventional cleaning processes. Those chemicals can lead to adverse effects. The federal level as well as the state level policy demands the elimination of trace components in the effluent of WWTPs by a progressing treatment stage. There are several advanced treatment processes, one example is the ozonation. Based on that a commercial-scale plant should be installed to the WWTP "Aachen Soers" associated to the project DemO_3AC. This WWTP is located in the city of Aachen and releases its effluent to the River Wurm. At medium and low water the river runs around 70 % treated waste water. To give evidence how the ozonation influences the ecological state of the River Wurm and the effluent of the waste water treatment plant the status quo of the river as well as of the WWTP are evaluated. Before testing those samples a sample pretreatment was conducted via a solid phase extraction over Oasis HLB cartridges with Methanol and Dichloromethane. For each sample site 2.5 l of water were filtered and extracted. After evaporating the samples and drying under a constant nitrogen stream the extract was dissolved in Dimethylsulfoxide to reach a final concentration of 2500 fold. Those samples are tested in several mechanism specific bioassays. Based on the results of the MTT assay – an assay by which the cytotoxicity of samples for different cell lines can be tested – the ERα CALUX assay evaluating the ERα Receptor mediated effect as well as the H295R assay evaluating the human steroidogenesis are conducted. To get information on the genotoxic effect of the samples the AMES assay with the bacteria strains TA 98 and TA 100 is carried out. First results for the AMES assay, the MTT assay as well as for the CALUX assay are generated but not yet finally evaluated. Those results will be available for the conference. Based on the results of the evaluation of the status quo a test battery for waste water evaluation should be developed.

TH104

Spotting opportunities amidst environmental degradation: Indigenous soil bacteria of mining sites.

O.G. Oladipo, North-West University / Unit for Environmental Sciences Management; O.T. Ezeokoli, M. Maboeta, J.J. Bezuidenhout, C.C. Bezuidenhout, North - West University / Unit for Environmental Sciences and Management

Diverse anthropogenic activities have resulted to heavy metal pollution and hence environmental degradation, posing huge challenges on soil and water resources as well as human health safety. Indigenous microbes from these degraded environments have proved to be valuable eco-friendly tools in the restoration of such environments. This study investigated the heavy metal resistance profile of bacteria for possible bioremediation strategy. Bacteria were isolated from soils collected from three active gold and gemstone mine sites in South - western, Nigeria. These were identified using 16S rRNA gene analysis. Isolates were exposed to five heavy metal concentrations viz: mercury (Hg), cadmium (Cd), lead (Pb), copper (Cu), nickel (Ni), aluminum (Al), manganese (Mn), zinc (Zn), iron (Fe) and chromium (Cr) supplemented into broth media. Growth absorbance was recorded by Micro well 96 well plate reader at 520 nm wavelength every 30 minutes for 48 hours. Minimum inhibitory concentrations (MICs) were then determined from the growth curves generated. Identified bacterial isolates were: *Lysinibacillus macroides* (LM), *Achromobacter spanius* (AS), *Bacillus kochii* (BK), *Klebsiella pneumoniae* (KP), *Pseudomonas mosselii* (PM), *Pseudomonas nitroreducens* (PN) and *Bacillus cereus* (BC). All isolates showed resistance to Pb, Ni, Mn, Fe and Al to highest concentrations >300, 100, 600, 600 and 100 ppm respectively while PN, KP, BK, AS and BC showed resistance to Zn (>300 ppm concentration). A 25 ppm Hg, Cr >100 ppm and Cd >50 ppm were tolerated by PN, PM and KP, while BK, AS and BC tolerated higher concentrations at Hg (>50 ppm), Cr (>150 ppm) and Cd (>100 ppm). *Pseudomonas nitroreducens*, PM, BK, AS and BC expressed tolerance to Cu >200 ppm concentrations. The heavy metal concentrations to which these bacteria showed resistance exceeded set permissible limits for contaminated soils globally. These results therefore suggest these bacteria isolates as potential bioremediation candidates for restoration of heavy metal polluted environments.

TH105

Bioremediation of oil-polluted soil in Caspian Sea coast by biodegradation bacteria

A. Charmi, Khoramshahr university of marine science and technology / Department of Marine Biology Faculty of Marine Science; F. Najafi, department of biology, faculty of sciences,Guilan university, Iran

The quality of life on Earth is linked inextricably to the overall quality of the environment. Bioremediation is an option that offers the possibility to destroy or render harmless various contaminants using natural biological activity. In this research 7 genera of biodegradation bacteria which are important in bioremediation process were isolated and identified. We had been used the soil sample of Amir Abad Chamkhaleh (the coast of Caspian Sea). Adding the soil samples to MSM (Mineral Salt Media) culture for isolating the biodegradation bacteria and then these bacteria inoculated to some media which had hydrocarbon as a carbon source and after isolating with alternative culture these bacteria were considered and characterized based on morphological biochemical and fermentation tests. According to the Bergy manual of systematic bacteriology these bacteria were identified. Although, in this study we had been used of plasmid extraction method for considering that if biodegradation genes exist in the plasmid or linear DNA .

Assessment of the potentail of biochar and coal tailings as atrazine sorbents

J.B. da Costa, UFRGS / Analytical Chemistry; D.P. Dick, Federal University of Rio Grande do Sul / Physical Chemistry; V. Maciel, Universidade Federal do Rio Grande do Sul

The intensive application of organochlorine pesticide results in the contamination of ground and surface waters. The objective of this study was to investigate the potential of carbonaceous matrices in the treatment of water contaminated by the herbicide atrazine (ATZ) by evaluating the sorption capacity of ATZ by biochar and nitrated coal tailing samples. Adsorption of ATZ was conducted both on the original coal tailings as on the nitrated samples. The nitration was conducted at 70°C under reflux (sohxlet) employing 25% HNO_3solution. In centrifuge tubes of 50 mL, 0.3 g of adsorbent were weighed and 30 mL of ATZ solution were added, at concentrations of 0, 1, 2, 4, 5 and 10 mg ATZ L^{-1} ($CaCl_2$ 0.01 mol L^{-1} medium). After 24 hours stirring in the dark, the suspension was centrifuged (2500 rpm for 15 minutes) and the supernatant was filtered and stored in dark bottles. Aliquots of the supernatant were taken for determining the concentration of atrazine in equilibrium in the solution by ultraviolet-visible spectroscopy (UV-Vis, UV-160 Shimadzu) at 222 nm. In all tested sorbents the tadsorption was reversible, indicating that these materials can be reused. The nitration of coal tailings improved their adsorption capacity and this behaviour was related to a change of the surface morfology rather to the increase of surface hydrophilicity. Nevertheless the adsorption capacity of nitrated samples was inferior to that of activated charcoal.

TH107

Butadiene Chemical Substance Flow Analysis in South Korea

J. Kim, Inha University; J. Kim, University of Technology of Troyes / Department of Humanities Environment Information Technology CREIDD; J. Moon, Y. Hwang, Inha University

Currently chemical substances and materials are widely used in all kind of industry and household, almost everywhere and in everything. On the other hand, many accidents related with chemicals are also occurring in the world. In South Korea, the accidents related with chemicals are getting increased from 7 cases in 2006 to 104 cases in 2014 (MOE, 2015). Along with establishment of chemical regulations such as EU REACH and Korea REACH - The Act on the Registration and Evaluation of Chemicals), many studies should be conducted for sustainable chemical substance's safety management and prevention of the chemical accidents. In this study, butadiene (1,3-Butadiene, C_4H_6, CAS NO: 106-99-0) in the important chemicals was selected. The butadiene is flammable, colorless gas with a mild aromatic odor and it is highly reactive. Butadiene is soluble in alcohol and ether, insoluble in water and polymerizes readily, particularly if oxygen is present. One major use of butadiene has been in the making of synthetic rubber. Butadiene is also used extensively for various polymerizations for plastics manufacturing. The purpose of this study, therefore, is to quantify, analyse and make a flow map of the butadiene by applying substance flow analysis (SFA). Our result shows that the amount consumption in each company, location of manufactures using butadiene as well as butadiene's flow (import, export, stocks and flows) in Korean industrial system (between industries including companies). Finally the result of this study can support for chemical accident prevention system and sustainable chemical management in South Korea.

TH108

A Study on Hydrogen Fluoride Substance Flow Analysis : In Case of the Chemical Industry in South Korea

M. Yoo, Inha University; J. Kim, University of Technology of Troyes / Department of Humanities Environment Information Technology CREIDD; J. Moon, Y. Hwang, Inha University

Up to date, many chemical accidents were occurred in the world. We know that recently there was a big chemical explosion accident and its expose of toxic chemicals in Tianjin, China. According to the Korean Ministry of Environment, the number of chemical accidents was increased 7 cases in 2006 to 104 cases in 2014. Therefore, it should be considered and conducted many studies on sustainable chemical substance's safety management and prevention of the chemical accidents as well as establishment of related chemical management regulations. In this study, we selected and studied about hydrogen fluoride (the chemical formula HF, CAS NO: 7664-39-3). This colorless gas or liquid is the principal industrial source of fluorine, often in the aqueous form as hydrofluoric acid, and thus is the precursor to many important compounds including pharmaceuticals and polymers (e.g. Teflon). HF is widely used in the petrochemical industry and is a component of many superacids. In this study, we quantified, analysed and mapped the HF flows in the chemical industry of South Korea by applying substance flow analysis (SFA). Our result shows that the amount of consumption in each company (and industry), location of manufactures using HF as well as HF's flow (import, export, stocks and flows) in Korean industrial system (between industries including companies). Finally the result of this study can support for chemical accident prevention system and sustainable chemical management in South Korea.

TH109

A Study of Ammonia Substance Flow Analysis in South Korea

K. Lee, Inha University; J. Kim, University of Technology of Troyes / Department of Humanities Environment Information Technology CREIDD; J. Moon, Y. Hwang, Inha University

Currently many chemical regulations such as EU REACH and Korea REACH are effected to chemical industry directly. With this regulation, it is required more assessment tools and methods for sustainable management in as well as accidents related with chemicals. Although there has been many researches on how to prevent chemical accidents and manage chemicals, very little attention has been paid on chemical substance flow in country level. For this study, ammonia chemical substance was selected. Ammonia or azane is a compound of nitrogen and hydrogen with the formula NH_3 (CAS number 7664-41-7). It is a colourless gas with a characteristic pungent smell. Ammonia contributes significantly to the nutritional needs of terrestrial organisms by serving as a precursor to food and fertilizers. About 80% of the global ammonia production is consumed by the fertilizer industry; specifically, 48% of the ammonia produced is deployed in the production of urea (the most commonly used nitrogen fertiliser and basic feedstock for industrial products like plastics, resins and adhesive) (Potashcorp, 2013). By using material flow analysis method, ammonia substance flows in South Korea was shown in this study. Required data such as import, export, production and consumption was collected from industry, association and national statistic department. Also spatial location information of manufacturing companies was analysed. Finally this study can support for the chemical accident and risk prevention system and sustainable chemical management in South Korea.

TH110

The DemO3AC Project - Ecotoxikological investigations of an ozonation treatment in the waste water treatment plant Aachen Soers (Germany)

S. Schiwy, Institute of Environmental Research-RWTH Aachen / Department of Ecosystem Analysis ESA

The European Water Framework Directive aimed to achieve a good ecological and chemical status in all European surface waters until now. However, only 20 % of German surface waters achieved these goals. One reason for this could be anthropogenic pollutants coming from wastewater treatment plants (WWTP).

These pollutants were not completely eliminated in the treatment process and thus enter the aquatic environment. Hence, in the DemO$_3$AC-Project a case study is conducted to demonstrate the implementation of a further treatment step, an ozonation process, to eliminate these pollutants in the WWTP. In this project different ecotoxicological bioassasy were applied to evalute and optimize them in focus for the application in water quality assessment of the river Wurm and the effluent of the WWTP. The river Wurm carries about 70 % of the treated wastewater at low and medium water levels. First, the *Status quo* of the water will be determined and then compared with the data after the implementation of the large-scale ozonation facility. With the standardized test methods for effluent assessment in accordance with DIN and ISO (bacteria, algae, daphnia and fish embryotoxicity) acute and chronic effects of anthropogenic trace substances at different trophic levels will be examined. In addition, cell-toxicological test systems will be used to investigate the estrogenic activity, effects on steroidogenesis and the mutagenic effects of the river water and effluent of the WWTP. On the organisms level *in vivo* and *in situ* studies are planned with the rainbow trout (*Oncorhynchus mykiss*), the mud snail (*Potamopyrgus antipodarum*) and the freshwater shrimp (*Gammarus spp*.). After evaluation the sensitive and most informative tests will be selected. These selected bioassays will be applied for the second stage of the project after the implantation of the new treatment step in the WWTP. A comprehensive chemical analysis of trace substances will be conducted by the Institute of Environmental Engineering (RWTH Aachen, Germany), at the same time-points. In addition, studies on the microbiological composition and antibiotic resistance will be conducted by the Institute of Applied Microbiology (RWTH Aachen, Germany). The project is funded by the Ministry for Climate Protection, Environment, Agriculture, Conservation and Consumer Protection of North Rhine-Westphalia.

TH111

Agrochemical loading in drain and rivers with connection with coastal lagoons in North of Sinaloa, Mexico: a potential risk linking to harmful algal bloom

C. Ponce de Leon; O. Arellano Aguilar, Universidad Nacional Autonoma de Mexico / Department of Ecology and Natural Resources

Ocean algal blooms have been related to nutrient accumulation in coastal lagoons in the Pacific Ocean. It is speculated that this nutrient overflow has its origins from the agricultural lands in northern Mexico. Sinaloa has a planted area of a million and a half hectares representing 38% of the vegetables produced in the country and ranking first in the production of grains it also excels in the export of sesame and corn. The value of agricultural production in the state varies in the range of 2 million euros a year and participates with six percent of the national agricultural GDP. Currently, annual pesticide application has been calculated to be 700 tons of 17 different types of pesticides which are classified from moderately to strongly toxic according to WHO. This intensive use of agrochemicals has led to the contamination of water bodies and sediments in the area. Therefore, this study aimed to determine the nutrient load and more persistent chemicals (organochlorine pesticides), chemicals that are subject to the Stockholm Convention. These compounds were determined in surface water bodies of Culiacan Valley, particularly in rivers and drains, as well as in the coastal lagoons that the studied rivers and drains fall into. According to the results, except for the Sinaloa and Culiacán rivers, organochlorine pesticides were detected in all samples, from which the only pesticide absent was heptachlor. According to the Rights Act recommended maximum concentrations for the protection of aquatic life in freshwater, brackish or coastal water ecosystems, all sampling sites where pesticides were detected in the water column, exceeded the maximum water quality guidelines for the protection of aquatic life. In most of the studied sites, concentrations of ammonium nitrogen as ammonia, nitrate, nitrite and phosphate, significantly exceeded the maximum allowable limits for the protection of aquatic life guidelines established in the Law on Water Rights, for both freshwater and coastal. These results could be related to harmful algal bloom in the area.

TH112

Phospholipid fatty acid profiles as indicators of microbial community composition variations in soil by mixed heavy metal pollution

M. Pukalchik, Lomonosov Moscow State University / Faculty of Soil Science; V. Terekhova, Institute of Ecology and Evolution RAS / Lab Ecologicall Soil Functions; E.V. Fedoseeva, Pirogov Russian National Research Medical University / Medicobiological faculty; K. Kydralieva; O. Yakimenko, Moscow State University / Soil Science Faculty; N. Verkhovtseva, Lomonosov Moscow State University (MSU) / Faculty of Soil Science

Primary information on heavily contaminated urban areas comes from many cities, however, chemical pollution assays are unable to evaluate the integrated biological effect, which shows a 'cocktail' of environmental factors acting simultaneously on biological systems. This study focuses at assessing of the microbial community structure of urban soils by phospholipid fatty acid analysis (PLFA). The soil samples(topsoil layer 0-20 cm depth) were taken at six sites located in the rural part of the cities of Kirov (Russia), differently polluted with heavy metals.The samples were measured for pH and the contents of organic C, total N, total P and total Pb, Ni, Cr and Cd. The structure of soil microbial communities was assessed using PLFA analysis (high-performance liquid chromatography–mass spectrometry method).The total PLFA content in control sample were found to be significantly higher than the polluted soil. The greatest indication value was given to an *Actinobacteria phylum,* their concentration decrease remarkably in the polluted samples, and anaerobes *Butyrivibrio* sp. and *Bifidobacterium* sp.were found as indicator of soils under relatively low soil pollution status.The microbial profileswere also indicated a selective enrichment of competent species (*Desulfovibrio* sp., *Bacteroides fragilis, Chlamydia* sp., *C. trachomatis*) in soil with high heavy metals contamination. Nonmetric multidimensional scaling plots of soil communities, showing the relative differences in control and pollution soils.Overall, our studycould promote to better understand how microbial community structure might adapt to heavy-metals stress. This study is supported by RSF (14-50-00029).

Multiple stresses in aquatic ecosystems: Assessment of stress response and its consequences in organisms (P)

TH113

Current and emerging issues in bivalves ecotoxicology

F. Gagne, Emerging Methods, Environment Canada / Emerging Methods; C. André, C. Auclair, C. Gagnon, Environment Canada / Aquatic Contaminants Research Division

The lifestyle of bivalve populations makes them species at risk to anthropogenic stressors such as pollution, loss of habitats and climate changes. Indeed, mussels are sessile organisms and could live to relatively long periods in some species (up to decades if not centuries). It is anticipated that global changes are likely to have local impacts on biodiversity. In this sense, local mussel populations are directly impacted by upstream disturbances such as urban effluents discharges and loss/modification of habitats. They are filter-feeders from which they trap and concentrate micro-particles in the digestive gland which represent a major vector for contaminant exposure in mussel tissues. For these reasons, bivalves were selected as sentinel species to assess the toxicity of emerging contaminants such as nanotechnology, oil sand products, endocrine disrupters from municipal discharges and changes in the microbiome. The cumulative effects of complex mixtures and other stressors in these times of climate change were also examined at the molecular and cellular levels in the attempt to identify adverse outcomes pathways leading to the decline of mussel populations. Exposure to xenobiotics increase the susceptibility to temperature changes at the electron transport steps in mitochondria which could increase energy expenses in bivalves at polluted sites under thermal fluctuations. Exposure to municipal effluent and zinc oxide nanoparticles both elicit oxidative stress which could lead to inflammation and phagocytosis suppression. Recent studies also showed that air time survival could also be shortened in mussels exposed to nanoparticles and oil sand contaminated environments which support the contention that mussels are species at risk from urban activities. Studies dealing on the cumulative effects of environmental stressors were also performed. Issues: Cumulative effects (nano and ME /Vibrio and ME), Climate change (SOS), endocrine disruption (feminization)/ emerging compound (pharma/OS) and molecular approaches for biodiversity studies (eDNA).

TH114

Evaluation of the health status of the blue mussels Mytilus edulis from two contrasted sites in the Bay of Seine (Normandy, France): A seasonal, transcriptomic survey.

A. MESNIL, Universite de Bretagne Occidentale / IUEM; K. Costil, University of Caen Normandie / UMR BOREA Biologie des Organismes et des Ecosystèmes Aquatiques MNHN UPMC UCBN CNRS IRD; A. Séguin, Université de Caen Normandie / UMR BOREA Biologie des Organismes et des Ecosystèmes Aquatiques MNHN UPMC UCBN CNRS IRD; B. Rocher, Universite du Havre / UMRI SEBIO; M. Auffret, Universite de Bretagne Occidentale / LEMAR; J. Lebel, Université de Caen Normandie / UMR BOREA Biologie des Organismes et des Ecosystèmes Aquatiques MNHN UPMC UCBN CNRS IRD; A. Serpentini, Universite Caen Normandie / UMR BOREA Biologie des Organismes et des Ecosystèmes Aquatiques MNHN UPMC UCBN CNRS IRD

The blue mussel *Mytilus edulis* is a common bivalve forming large populations on natural and artificial hard substrates. These sessile, filter-feeder organisms are able to bioaccumulate and/or metabolize and tolerate a wide range of pollutants, sometimes at high concentrations. They have been extensively used as bioindicators and sentinel species to assess coastal water quality, especially in estuaries. However, mechanisms by which mussels can survive in such polluted environment are not completely understood. In this context, indigenous mussels were sampled every 3 months during a full annual cycle at two contrasted sites situated on the English Channel coast in Normandy (France): Villerville-sur-Mer (Normandy, France) located at the mouth of Seine estuary, a site highly affected by contaminants originating from agricultural runoff, urban sewage, inputs from industrial plants, and Yport (reference site) located on the north of Le Havre which is not directly exposed to the inputs of the Seine river. Previous studies have demonstrated that a large set of biological endpoints are necessary to detect stress responses generated by a complex contamination in highly variable ecosystems. Hence, a battery of molecular and physiological markers was investigated to allow the characterization of the spatio-temporal variation of the health status of mussels located in the two studied sites. Biomarkers corresponding to energetic metabolism, immunity/inflammation, stress and detoxication were investigated at the transcriptional level (a total of 43 genes) in both gills and digestive gland. In addition, a condition index was calculated and histology was performed in order to assess the health and reproductive status as well as the sex ratio of the mussels. Indeed, in marine bivalves, reproduction is a major biological function especially costly in energy. Results indicated that variations of biomarker responses were associated to seasonal variations, the contaminant levels in the environment and the reproductive status of organisms. These results showed the ability of mussels exposed chronically to contaminations to acclimate to their environment which may contribute to their survival in theBayofSeine. This work was supported by a grant from both ANR and NSERC Agencies (joined France-Canada project) as a part of the research programme IPOC (Interactions between POllution and Climate changes: Development of improved monitoring strategy, ANR-12-ISV7-0004-01, 2013-2015).

TH115

Molecular response of mussels Dreissena sp. to contrasted environments: comparison of different French and Canadian populations

E. Kerambrun, L. Evariste, Université de Reims Champagne Ardenne / UMRI SEBIO; D. RIOULT, UMRI 02 INERIS-URCA-ULH SEBIO / MOBICYTE flow cytometry core facility; L. Delahaut, Université de Reims Champagne Ardenne / UMRI SEBIO; B. Rocher, Universite du Havre / UMRI SEBIO; S. Pain-Devin, Université de Lorraine - UL / LIEC CNRS UMR; S. Devin, LIEC - Université de Lorraine - CNRS / LIEC CNRS UMR; P. Cloutier, M. Desrosiers, CEAEQ; A. Geffard, Université de Reims Champagne Ardenne; M. Fournier, INRS-Institut Armand Frappier / ISMERUQAR; M. Auffret, Universite de Bretagne Occidentale / LEMAR; E. David, Université de Reims Champagne Ardenne / UFR Sciences Exactes et Naturelles

Zebra mussels from gender *Dreissena* are classically used as model species in ecotoxicological studies assessing freshwater ecosystems quality. These filter feeders sedentary bivalves are considered to faithfully represent their living environment. Numerous biomarkers have been developed in dreissenids as tools of freshwater ecosystems biomonitoring. In the context of IPOC franco-canadian research program (Interactions between POllution and Climate changes: development of improved monitoring strategy), *Dreissena sp*. was retained as freshwater model mussel to evaluate biological effects of combined action of pollution and climate change, following French and Canadian populations health. Populations of mussels from four rivers in the north of France (Vilaine, Moselle, Meuse and Oise) were sampled in spring and autumn. In parallel, Canadian populations of mussels from four different sites along the St Laurent River were also sampled in autumn. Condition index was measured. Contaminants contents were analyzed. Molecular response of the different populations were assessed through the following of gene expression by real-time PCR. Candidate genes were chosen for their involvement in cellular energy metabolism (cytochrome-C-oxidase, ATP synthase), antioxidant systems (catalase, superoxide dismutase, glutathione peroxidase) and xenobiotics detoxification (glutathione-S-transferase, metallothionein). Results showed that French mussels tend to present a higher expression level for most of genes in the site considered as the less contaminated. In this site, seasonal variations were more pronounced than in the three others, with expression levels of candidate genes lower in autumn than spring. First genetic analysis also revealed that some French mussel samples presented two dreissenid species: zebra mussel *Dreissena polymorpha* but also quagga mussel *Dreissena rostriformis bugensis*. This second species appeared as the most widely represented in Canadian populations. As in French populations, expression levels of chosen genes were often higher in mussels sampled in the less anthropized site of the St Laurent. This study shows that mussels from different sites could be discriminated with expression gene responses, what constitutes a promising point to evaluate population health status.

TH116

Physiological state and metal bioaccumulation in mussels, Mytilus edulis, transplanted into a mesohalin marina in Normandy (North West France)

A. Séguin, C. Caplat, Université de Caen Normandie / UMR BOREA Biologie des Organismes et des Ecosystèmes Aquatiques MNHN UPMC UCBN CNRS IRD; A. Serpentini, Universite Caen Normandie / UMR BOREA Biologie des Organismes et des Ecosystèmes Aquatiques MNHN UPMC UCBN CNRS IRD; J. Lebel, Université de Caen Normandie / UMR BOREA Biologie des Organismes et des Ecosystèmes Aquatiques MNHN UPMC UCBN CNRS IRD; K. Costil, University of Caen Normandie / UMR BOREA Biologie des Organismes et des Ecosystèmes Aquatiques MNHN UPMC UCBN CNRS IRD

Mussels are often used as sentinel organisms in biomonitoring surveys performed in coastal environments such as Mussel Watch Program (NOAA; USA) or ROCCH (IFREMER; France). *Mytilus ssp* are well adapted because they are sessile, filter-feeder and euryoecious mollusks. Environmental monitoring surveys generally include one-off sampling in the year and do not take into account the temporal variations in contaminant burden and biological parameters. Moreover, the fluctuation of environmental parameters can constitute confounding factors in the detection of species responses to habitat contamination. In this context, we assessed the monthly variability of the bioaccumulation of trace metals and a battery of biomarkers in mussels caged in a constraining environment. Before the beginning of the experiment, a batch of *Mytilus edulis* originating from Chausey Islands (English Channel, Normandy, France) was progressively acclimated to low salinities (from 32 to 12 PSU). Then, mussels were continuously caged into the marina of Carentan (Normandy) which is predominantly supplied with freshwater from two rivers but also influenced by seawater from the Bay of Veys. Finally, this marina can be considered as a mesohalin station where we placed a high-frequency probe which recorded temperature and salinity. In 2015, samples of water and mussels were monthly collected for metal analyses, and various endpoints at different levels of biological organization were studied. Individual biomarkers included the assessment of mortality and growth rates, and histology allowed to determine the reproduction success and tissue quality (histopathology). The regulation of oxidative stress was evaluated by measuring both enzymes activities (catalase and glutathion-s-transferase) and the final product of lipid peroxidation (malondialdehyde). Neutral red uptake assay gave information about lysosomal system while flow cytometry approach provided data about reactive oxygen species (ROS) and hemocyte phagocytic activity. One month after the beginning of the study, high mortality rates were recorded but then mussels showed a high ability to survive (up to 10 months) in a contaminated environment where salinity greatly varies and where mussels had thus to face multiple stresses. The present study highlighted the temporal fluctuations of some endpoints and these variations should be taken into consideration in the interpretation of data obtained from biomonitoring surveys.

TH117

A step forward in multixenobiotic resistance: first evidence of ABCG2-type gene expression and effect of season change and contaminants on ABC mRNA expression in gills and hemocytes of the blue mussel

Y. BEN CHEIKH, SEBIO UNIVERSITE LE HAVRE; B. Xuereb, SEBIO UNIVERSITY OF LE HAVRE; C. Boulange-Lecomte, A. Duflot, SEBIO UNIVERSITY OF LE HAVRE / UMRI SEBIO; J. Danger, F. Le Foll, SEBIO UNIVERSITY OF LE HAVRE

Multixenobiotic resistance (MXR) is a powerful defence system mediated by transmembrane proteins known as ATP binding cassette (ABC) transporters that bind and actively remove xenobiotics from the cell. The aim of this study was i) to identify the gene encoding the breast cancer resistance associated protein (BCRP) in hemocyte and gills of *Mytilus edulis*, ii) to explore the effect of season change and site pollution on the gene expression of three ABC transporters identified in the blue mussel (ABCB, ABCC and ABCG2) and iii) to correlate transcripts levels in gills with efflux transporter activities. The expression of ABCG2/BCRP transporter was investigated in gills and hemocyte extracts by RT PCR and 5'-RACE. The PCR products had the expected size in both tissues. The identified partial cDNA sequence of ABCG2 overlapped with ABCG2 homologues of other organisms from 72 % to 98 %. The expression quantification of abcb-like, abcc-like and abcg2-like genes was carried out using RT-QPCR on mussel's extracts collected during 4 seasons from areas identified by the program IPOC (Interactions between POllution and Climate changes) for being differentially impacted by chemical contaminants in Normandy. Results indicate that transcripts levels of ABC transporters in gills and hemocytes significantly fluctuated along seasons. Overall, we observed an increase in ABC gene expression during February for both tissues. In hemocytes, abcb-like and abcg2-like transcripts were more abundant in mussels originating from the control site during February than those collected from the contaminated site at the same period. The trend was reversed for the other seasons where abcg2-like expression increased significantly in the control area. Furthermore, no relevant change was noticed for abcc-like expression. In contrast, gills exposed to pollutants showed a higher abcb-like and abcg2-like transcript levels in February and conversely a lower abcg2-like expression while no difference was noted for the other seasons. We also studied the efflux activity by measuring the accumulation of calcein in gills in presence of ABCB and ABCC blockers. A higher transporter activity was measured in tissues obtained from the contaminated site which is concordant with the transcripts levels. All together, the present results suggest the regulation of ABC transporters by season change and water contaminants besides their involvement as protective and tissue specific response xenobiotics.

TH118

Effects of a realistic multiple low dose pesticide exposure scenario on aquatic communities in stream mesocosms

R. Gergs, Umweltbundesamt; S. Mohr, Umweltbundesamt / IV; C. Winkelmann, University of Koblenz-Landau - Institute of Natural Sciences / Department of Biology; J. Zubrod, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; S. Meinecke, M. Feibicke, Umweltbundesamt

The current common EU risk assessment for pesticides refers to effects of single substances. As one result of this risk assessment a regulatory acceptable concentration (RAC) for each pesticide is estimated, which should not lead to any inacceptable adverse effect on non-target organisms in freshwater systems. However, in agriculture combinations of different pesticides are repeatedly used over time and space to protect crop from pests. Hence, communities inhabiting streams in agricultural landscapes are exposed to mixtures of pesticides and their metabolites, which might cause a multiple-stress scenario for these non-target organisms. For example, in orchards a high number of pesticides with different modes of action are repeatedly applied in short time intervals during the whole vegetation period. However, potential additive or even synergistic effects of realistic exposure scenarios are rarely investigated, especially on the community level. Here, we studied the effects of a realistic pesticide spray scenario for apple crop protection on aquatic communities in surface waters using eight indoor stream mesocosms. Aquatic invertebrates from a reference site were added to the stream mesocosms using colonized straw bags. Overall, nine fungicides, four insecticides and four herbicides were applied at their respective RACs for surface waters to each of the four treatment mesocosms within a period of two and a half months. At nineteen days altogether pesticides were used 36 times with up to four different pesticides per date. Most fungicides were used repeatedly up to seven times. In order to detect potential effects on the aquatic community we measured a variety of biological endpoints. We focused mainly on sublethal effects, which are more likely to occur in a multiple low dose pesticide exposure scenario. Potential short-term effects like behavioral changes within several hours were determined by measuring drift and activity patterns of benthic invertebrates. Long-term effects were measured by changes in the community composition of invertebrates and the emergence of merolimnic insects. Furthermore, we investigated potential effects within the food web structure using stable isotope analysis and fitness of invertebrates using the RNA:DNA ratio as proxy. We compared the results of different endpoints in order to quantify the impact of the multiple stress scenarios on different scales.

TH119

Identification of relevant toxicant mixtures influencing the macroinvertebrate community of the Danube river

A. Rico, Wageningen University / Environmental Risk Assessment Team; P. van den Brink, Alterra and Wageningen University / Aquatic Ecology and Water Quality Management Group; A. Focks, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team

Aquatic organisms inhabiting large rivers are exposed to a wide range of contaminants including down-the-drain chemicals (e.g. pharmaceuticals, food additives, home-care products), industrial pollutants (e.g. metals, PAHs) and pesticides. It is therefore evident that observed changes in biodiversity are likely to be explained by toxicant mixtures resulting in additive, synergistic or antagonistic responses at the individual, population and community levels. Besides the large number compounds and possible mixtures occurring in the environment, it is expected that only a limited number of substances are responsible for the observed biological responses. Identifying these chemical mixtures is key to understand their combined toxicity mechanisms and to derive responsible risk abatement options. The main objective of the current study was to identify toxicant mixtures that are influencing the macroinvertebrate community monitored in the Danube river. A large database obtained as part of the environmental monitoring campaign performed during 2013 in the Danube river was used in this study. The database contained abundance data for 393 invertebrate species monitored in 55 sampling sites of the Danube river, and measured chemical concentrations in each sampling site. The chemical dataset contained water concentrations for 227 chemicals, including pharmaceuticals, pesticides, PAHs, metals, food additives, and home-care products. Prior to the mixture toxicity identification, four biological indices were calculated that represent the macroinvertebrate community in each of the sampling sites. These were: taxa richness, total abundance of individuals, Shannon diversity index and species evenness. Chemical mixtures significantly influencing the variability in the community indices were identified by selecting best-fit Generalized Linear Models (GLMs) containing binary, tertiary, quaternary and quinary chemical combinations. The selection of best fitting models was performed using the RSELECT procedure in the GENSTAT software. The best fitting models were obtained for species richness, with R^2 values of up to 63%. Relevant chemical mixtures included, in most of the cases, pharmaceuticals (e.g. anti-depressive and anaesthetic drugs), insecticides, and some feed additives. Further research should aim to study the mechanistic link between the identified chemical mixtures and the community responses using laboratory and/or semi-field experiments.

TH120

Characterizing a nanocosm for the evaluation of toxicant effects on an aquatic community

V. Riedl, University of York / Environment Department; R. Benstead, Fera Ltd.; R. Ashauer, University of York / Environment

When organisms are exposed to toxicants they can be influenced directly when e.g. feeding or reproduction are impaired and indirectly when interactions with other system components are altered. These ecological effects can be studied in micro-/and mesocosms but they are expensive, time and labour demanding and, in general, few replicates are used. With ecological complexity the variability between replicates increases and an extrapolation of effect/response relationships is more difficult. In regulatory risk assessment, a tiered effect assessment approach is in use to evaluate the effects of pesticides on non-target organisms but only when the direct effect results of single-species tests (inexpensive, quick and repeatable) raise concern, are micro- or mesocoms employed. Few small systems have been developed to describe direct and indirect toxicant impacts on multi-trophic communities and they are rarely tested for reproducibility. This project aims to develop and characterize a small, multi-trophic aquatic test system to bridge simple single-species tests and complex multi-factor micro-/mesocosms. Species with short life cycles and fast reproduction times are used to keep test durations short and reproducibility is increased by using a simple test design. This allows the assessment of toxicant impacts on basic community processes and system dynamics, and the extrapolation of causal/mechanisms. The system will be challenged with pesticides and the outcome will be compared to the predictions made by an Individual Based Model (IBM) developed with data obtained in single-species tests. It will be evaluated whether effect data of system components are sufficient to predict community dynamics or if it is necessary to assess the impacts on the system as a whole (including species interactions). Here we present on overview of the nanocosm development, experimental protocols and control variability.

TH121

Oscillating population dynamics: chemostats to study direct and indirect toxic responses in simple prey-predator system

d.p. eidsvoll, Norwegian Institute for Water Research (NIVA); L. Nizzetto, NIVA Norwegian Institute for Water Research; A. Lillicrap, NIVA / Ecotoxicology and Risk Assessment

Keywords: Chemostats, *Daphnia magna*, algae, atrazine, Understanding the impacts of natural and anthropogenic stressors on ecosystems requires analyzing responses at the level of ecological interactions between individuals and populations. This obviously applies also to the analysis of the impacts of micropullutants in the environment. Traditionally, ecotoxicology opted for a highly reductionist frame focusing on responses of individual populations treated in static environments. This approach totally neglects the cascade of effects that chemical stressors can produce by influencing ecological interactions across competing groups or along a trophic chain. Excess of reductionism can therefore lead to misinterpreting the real scale of contaminant impacts in the ecosystem, while tolls for investigating propagation of effects at higher ecological levels are still not well established. We developed a chemostat-based tool which allow reproducing "simple", self-regulating and ecologically dynamic systems (e.g. primary producer-grazed system). Through the chemostats we conducted experiments to investigate chemical (or other stressors) impacts in a simplified, though fully functional, biological system. Chemostats with oscillating cycles of a primary producer population (*Pseudokirchneriella subcapitata*) and a grazer population (*Daphnia magna*) where obtained and maintained over 3 months. A set of chemostats were routinely spiked with Atrazine to maintain this photosynthesis inhibitor close to the $EC50_{algae}$ and below $NOEC_{Daphnia}$. The addition of the atrazine to the dynamic system modified trophic transfer affecting Daphnia population dynamics despite atrazine, at these exposure levels, did not have any direct effect on the grazer population. The Chemostat was therefore successfully used to illustrate how impact of chemicals can be transferred across trophic levels and produce implication for the biological system functioning as a whole.

TH122

The effect of selected biocides on algae communities in water bodies affected by stormwater runoff

D.A. Stephansen, G. Minelgaite, M. Simon, Aalborg University / Civil Engineering; J. Vollertsen, Aalborg University / Department of Civil Engineering

In urbanished areas many biocides are in use to prevent unwanted growth of organisms on e.g. construction materials and wood. Over time, the biocides leach from the urban materials and are transported with stormwater runoff to receiving water bodies. As biocides are non-selective, they can affect non-target organisms and thereby cause unintended harm to the surrounding environment. A common approach for stormwater management is to establish wet detention ponds. They fulfill dual purpuses. Firstly, they detain the runoff water during heavy rain and hereby reduce the hydraulic loads on the receiving waters. Secondly, they hold stormwater runoff for prolonged durations, allowing natural treatment processes to proceed. Due to their permanent water pool they furthermore present themselves as habitats for flora and fauna, and rapidly become populated with species similar to what is found in natural ponds. The biota in the stormwater ponds hence become subjected to the biocides from the building materials. This study focusses on four biocides; terbutryn, diuron, irgarol and carbendazim, and their effect on the algae growth and change in the community composition at conditions found in stormwater ponds. The biocides were studied in three test systems. Two were microcosms at controlled laboratory conditions with stabile temperature and a light exposure of 12 h per day. These ran for 10 days, with algae sampling at day 1, 5 and 10. The first setup was conducted in glass bottles filled with pond water. Water samples, from a wet detention pond in the city of Silkeborg, was collected from 5 locations allocate evenly in the pond and mixed thoroughly. The second controlled microcosms study was performed in glass sediment cores, filled with pond sediments and water from the same pond. For both setups, stock solutions of all biocides were added in varied concentrations. The third setup consisted of mesocosms placed in the pond from where also the water and sediments had been sampled. Here, the added biocides and algae community were exposed to natural changes in temperature, sunlight and rain. This experiment ran for 15 days, with algae and biocide sampling several times during the period of exposure. The development in algae communities and its dependence on biocide levels were compared in the 3 setups, yielding results on the impact of the biocides on community composition and on cell numbers and cell sizes.

TH123

ECOSCOPE: a mesocosm facility to evaluate stressor impacts on headwater streams across multiple levels of biological organization

S. Devin, P. Bauda, E. Billoir, LIEC - Université de Lorraine - CNRS / LIEC CNRS UMR; Z. Dang, RIVM / LIEC CNRS UMR; V. Felten, C. Pagnout, LIEC - Université de Lorraine - CNRS / LIEC CNRS UMR; D.A. Vignati, CNRS / LIEC UMR

Predicting long term consequences of stressors is a key challenge of environmental risk assessment. Most of the developed methodologies rely on either standardized toxicity tests (for *a priori* evaluation) or on well known bioevaluation methods (for *a posteriori* evaluation). However, long term effects of stressors on aquatic ecosystems are still poorly explored. Besides that, usual protocols generally focus on only one compartment and/or biological scale, neglecting biotic interactions, functional processes and more typically effect propagation, top-down feedback and ecological non-monotonic responses. To help the scientific community to address these issues, an outdoor mesocosm platform with 18 artificial channels of 3 meter long, with water circulation and roof system has been built to simulate headwater streams, and to explore the responses of the ecosystem set in place on the long term (several months), with a systemic approach taking into account several biological compartments (macroinvertebrates, bacteria, fungi, algae...). The channels are designed to allow for changes in flow velocity, thermal and chemical conditions and habitat structure, and, obviously to combine those abiotic parameters with contaminants to explore multi-stress conditions. They are equipped with sensors for a real-time tracking of temperature, oxygen concentration and pH. The platform is open for research project in collaboration with academia, stakeholders and private investigators.

TH124

A fish multi-biomarker approach, including main physiological functions, to better determined global effect of contaminant on ecosystem

A. Bado-Nilles, INERIS; O. Palluel, INERIS / INERIS UMRI SEBIO ECOT; E. Chadili, E. Maillot-Maréchal, Ineris UMR-I 02 SEBIO; J. Bouchard, ONEMA; J. Porcher, INERIS / INERIS UMRI SEBIO ECOT; W. Sanchez, Fondation de Coopération Scientifique Rovaltain

Risk evaluation, due to the presence of toxic compounds in the environment, brings up the necessity to better understand their global effect on ecosystem. In this way, in addition to traditional biochemical biomarkers, some laboratories proposed to study the responses of biomarkers in relationship with the main physiological functions (reproduction, survival, maintenance, behaviour). This approach favors the evaluation of links between biochemical responses and individual/population effects. In this context, a multi-biomarker approach was used in four stations of a French river (La Loue – Franche-Comté region) surrounding area of drastic fish mortalities. In each station, 20 bullheads of both sexes were caught in spring and autumn by electrofishing for further biomarker analyses. The major results shown that the global health indicator (index condition, lysosomal membrane integrity and lipoperoxydation), the indicator of reproduction (gonado-somatic index and the maturation stage), the biotransformation enzymes and chromosomique damages were never modified regardless to station. Nevertheless, immune response and neurotoxic activity were strongly modified in the stations with fish decline. All these results could imply an important immune request and/or the presence of neurotoxic compounds in the river, inducing fish mortalities. This study showed the relevance of using multi-biomarker approach, including main physiological functions, to better determined effects of various contaminants on ecosystem health.

TH125

The three spined-stickleback's digestive enzymes as new biomarkers in environmental monitoring: effect of cadmium and temperature

Y. HANI, C. TURIES, INERIS / INERIS UMRI SEBIO ECOT; E. Kerambrun, Université de Reims Champagne Ardenne / UMRI SEBIO; O. Dedourge-Geffard, University of Reims Champagne-Ardenne / UMRI SEBIO; J. Porcher, INERIS / INERIS UMRI SEBIO ECOT; A. Geffard, Université de Reims Champagne Ardenne

The three-spined stickleback, is a freshwater, brackish, and marine fish species with large distribution throughout the northern Hemisphere. This pollution-tolerant fish is present in most European streams and small rivers but also coastal and estuarian areas, which make it a suitable candidate for environmental monitoring and risk assessment of aquatic ecosystems. Several biomarkers have been developed for this animal model. This study aims at characterizing and developing a new category of biomarkers in relation with energy acquisition, in sticklebacks. Among these parameters, digestive capacities of many invertebrates and vertebrates aquatic organisms have demonstrated a good sensitivity to contaminants. Thus, in this context, the most important digestive enzymes were firstly characterized in this sentinel species, according to it diet, in optimal living conditions. Secondly male and female juvenile sticklebacks were exposed for 3 months in semi-static conditions to cadmium at $1\mu g.L^{-1}$ (chemical stress), and two temperature values 16°C and 21°C (physical stress). Water quality and cadmium concentration in the water were also monitored throughout the experiment. Parameters such as somatic indexes (height, weight, fulton's condition index) and digestive enzymes (trypsin, intestinal alkaline phosphatase and amylase) were measured at 15, 60 and 90 days interval after cadmium exposure. The results have demonstrated a significant decrease in biometric parameters, from the 3rd month, especially among groups subjected to a temperature of 21 ° C. Furthermore, we observed an important alteration of the activity of the different enzymes over time and especially for trypsin and alkaline phosphatase in individuals exposed to cadmium at 21°C suggesting interactions between chemical and physical stresses on biological responses. For the first time, the digestive enzymes of the three-spined stickleback are reported as new environmental biomarkers.

TH126

Pesticide effects on stream fungi in a realistic apple-crop exposure scenario

S. Carl, Goethe University Frankurt; S. Mohr, Umweltbundesamt / IV; R. Gergs, Umweltbundesamt; M.O. Gessner, Leibniz Institute of Freshwater Ecology and Inland Fisheries IGB; C. Baschien, Leibniz Institute DSMZ - German Collection of Microorganisms and Cell Cultures

Significant amounts of pesticides applied in agriculture may reach surface waters via spray drift or runoff. However, the impact of pesticides on aquatic fungi has rarely been investigated, although fungi in streams and other inland waters play a key role in the decomposition of organic matter such as plant litter. Here we assessed the effects of pesticides on aquatic fungi in a stream mesocosm experiment conducted in a large indoor stream facility. The experiment was designed to mimic a realistic apple-crop exposure scenario involving multiple low-dose pulses of pesticides. Our specific goals were to assess whether (i) quantitative polymerase chain reaction (qPCR) is a useful method to monitor the aquatic fungi abundance; (ii) aquatic fungi are affected by pesticide pulses at low doses; and (iii) individual fungal species can serve as indicators of pesticide impacts. Dried alder leaves (*Alnus glutinosa*) were inoculated with suspensions of homogenized mycelium obtained from two strains of aquatic hyphomycetes, *Tetracladium marchalianum* and *Neonectria lugdunensis,* and one strain of the ubiquitous fungus *Cladosporium herbarum* and exposed in eight stream mesocosms. Four mesocosms served as untreated controls. The other four were dosed seven times with six different fungicides, once with two herbicides and twice with two insecticides. 'Regulatory Acceptable Concentrations' (RAC) of these pesticides were applied on a total of eight days within two months. Up to four different fungicides were applied on a single day. Endpoints included abundance (qPCR) of the three target fungi, ergosterol as an indicator of total fungal biomass, and fungal spore production. Rates on leaf litter breakdown were also determined. Results are discussed in relation to their implications for risk assessment of pesticides.

TH127

Combined toxicity effects of binary pesticide mixtures on luminescence bacteria Vibrio fischeri

J. Jang, KIST Europe; J. Kim, KIST Europe / Environment and Bio Group; Y. Kim, Y. Kim, KIST Europe

Pesticide have been mostly used as plant protection products (PPP) for agricultural and non-agricultural purposes. Various pesticides released to the aquatic environment have been found in the form of mixtures. In this study, luminescence marine bacteria *Vibrio fischeri* was used as a target living organism to measure toxicities of 7 single pesticides (chlorpropham, dimethoate, diquat dibromide monohydrate, acetamiprid, clomazone, dazomet, and dodine) which were selected in a list of PPP and their 21 binary mixtures. Additionally, to classify the combined effects at equitoxic ratio, toxic units (TU) was calculated with concentration of single chemical in mixture divided by EC_{50} value of their single chemicals. Theoretically, the concept of 1TU is assumed as additivity, but the combined effects were classified as additivity when TU ranges from 0.8 to 1.2 considering human errors in this result. Based on TU values, 10% of total mixtures showed synergistic effect and 38% and 52% of mixtures indicated additive and antagonistic effects at EC_{50} level, respectively. As single chemicals, dimethoate, chlorpropham, dazomet, clomazone and acetamiprid seem to be closely related to synergistic effect, while the most number of dodine and diquat were found in antagonistic combinations, suggesting that dodine and diquat are strongly involved in antagonistic mechanisms. Interestingly, dodine was much more involved in combinations having antagonistic effects, though it had considerably higher toxicity than six pesticides at EC_{50} level.

TH128

Preliminary approach for the study of the effects of multiple stress factors on honeybees

M. Vighi, IMDEA Water Institute / Earth and Environmental Sciences; P. Tremolada, University of Milano / Deprtment of Biomolecular Sciences and Biotecnology; R. Giacchini, P. Parenti, University of Milano Bicocca /

Department of Earth and Enviromental Science; R. Benocci, University of Milano Bicocca; D. Lupi, University of Milano / Department of Food Environmental and Nutritional Sciences
Bee decline is a problem of high concern all over the world. Since the late '90s, a complex pathology (Colony Collapse Disorder: CCD) brought to widespread events of honeybee disappearance especially in the U.S. and in Europe. It was not always possible to relate them to a specific cause. Many adversities may be responsible of CCD events and of the general honeybee decline: recrudescence of old and new pathologies, environmental stresses, including climate change, contamination from pesticides and emerging contaminants (e.g. nanoparticles) and electromagnetic fields. All these factors may interact among them and show synergic effects or multiple exposure ways. This work is a preliminary attempt to evaluate the effect of combined stress factors (pesticide mixtures and electromagnetic fields) on honeybees. Three experimental sites where selected in northern Italy: a control site, far from agricultural field and from any significant human settlements; an agricultural site, located in a farm where different crops (orchards) are present with a complex and controlled situation of pesticide application; a semi-natural site, far from agricultural areas and close to an electric line generating a strong electromagnetic field. In each site some experimental hives were posed. The sites were sampled monthly from May to October 2015. At each sampling date a suitable number of bee (both workers and standing) were sampled for biochemical (acetylcholinesterase, lipid peroxidation, antioxidant enzymes) and genetic (Comet assay) biomarkers. Some observation were made on the health status of the colony. Moreover, electromagnetic field measurements were performed and samples of environmental matrices were collected for quantifying pesticide exposure and for calibrating suitable exposure models. Meteorological parameters were get from the meteorological station closer to each sampling site. The effects of different stress factors are evaluated and compared. The work will be used as pilot project for the development of a more extensive research project on multi-stress effects on bee decline.

TH129
The sublethal effects of epoxiconazole and α-cypermethrin toward Daphnia magna reproduction and neonates' size
M. Gottardi, University of Copenhagen / Department of Plant and Environmental Sciences; M.R. Birch, University of Copenhagen; N. Cedergreen, University of Copenhagen / Plant and Environmental Sciences
Azole fungicides and pyrethroid insecticides, two classes of pesticides commonly used in agriculture, can reach surface water due to spray drift and run off after rain events. Because of the opportunity of both azoles and pyrethroids to enter surface water, and since azoles have been shown to synergize the effect of pyrethroids, the effect of their mixture is of concern. In particular, the sublethal effects of low concentrations are of interest, since these are the concentrations most often occurring in the environment. Beside the commonly described adverse effects of pesticide exposure on mortality, growth and reproduction, it is also generally recognized, that exposure to low doses of insecticides may result in hormetic responses. Hormesis is defined as a biphasic response, where the effect of exposure to low doses is opposite than the effect at high doses. One of the proposed explanations for hormesis due to low concentrations of insecticides is an initiation of the induction of detoxification enzymes such as cytochrome P450. The aim of the present study was to investigate the effect of sublethal doses of an azole fungicide (epoxiconazole) and a pyrethroid insecticide (α-cypermethrin) and their mixture on growth, reproduction and *in vivo* cytochrome P450 activity of the aquatic crustacean *D. manga*. The study was designed to investigate the following hypotheses: 1) azole fungicides act as synergists of pyrethroid insecticides also at sublethal endpoints such as growth and reproduction 2) a possible trade-off between size and number of neonates may be present for the organisms exposed either to single compounds or to the mixture and 3) low doses of epoxiconazole stimulate cytochrome P450 activity *in vivo* thereby a) increasing the detoxification of α-cypermethrin resulting in less harm to reproduction or b) increasing metabolic costs of detoxification leading to lower growth and/or reproduction. The experiment was designed to separate and count neonates over time, while measuring length and protein content of mothers and neonates as well as cytochrome P450 activity of mothers over time. The cumulative reproduction of *D. magna* varied according to time and exposure. The reproduction observed in the different treatments will be compared and associated with length and protein content of both mothers and neonates and with cytochrome P450 activity of the mothers in order to address the three hypotheses.

TH130
Physiological state and metal bioaccumulation in the alien mussel, Mytilopsis leucophaeata, sampled in a freshwater site and a mesohalin marina in Normandy (North West France).
a. séguin, University of Caen Normandie; C. Caplat, UMR Borea / physico chemical; A. Serpentini, Universite Caen Normandie; J. Lebel, Université de Caen Normandie / UMR BOREA Biologie des Organismes et des Ecosystèmes Aquatiques MNHN UPMC UCBN CNRS IRD; C. Katherine, UMR Borea
The brackish water mussel, *Mytilopsis leucophaeata* is a species from the Dreissenidae family originated from the south of U.S. Atlantic coast (Mexico Gulf to Hudson River Estuary). Nowadays, this species spreads in Europe from Spain to Scandinavian countries, and is considered as a potential invasive species. By comparison to other mussel species such as *Dreissena polymorpha,* few studies have been conducted on *M. leucophaeata,* and most of them were performed on antifouling solutions and its new distribution areas while very few studies dealt with ecotoxicology. However, *M. leucophaeata* should be well adapted to biomonitoring surveys as this species is sessile, filter-feeder and euryoecious. Moreover, this species can live in a wide range of habitats from freshwater to mesohalin areas giving the possibility of environmental monitoring along the land-sea continuum. The aim of this one-year study was to evaluate the adaptation mechanisms developed by *M. leucophaeata* in two contrasted areas (a marina and a river) through the monthly monitoring of metallic contamination and a battery of biomarkers at different levels of biological organization. The battery of selected biomarkers included endpoints from individual scale (survival, biometric parameters) down to infra-individual descriptors, such as histological (determination of gender and gametogenesis stages) and biochemical biomarkers (activities of glutathione-S-transferases (GST) and catalases (CAT), and malonedialdehyde as a marker of lipid peroxidation).The results currently available show a greater contamination by trace metals in mussels from the marina with higher concentrations in Cu (up to 10-fold) and Cd (up to 3-fold). Moreover, 4 months after the beginning of the study (mid-April), mussel mortality rates are high, especially in the marina where they reach ~98% *versus* 41% in the freshwater site. At all sampling dates, the mussels from the marina are globally smaller and lighter, and show a poorer condition index. Regulation of oxidative stress does not reveal significant differences between the individuals from the two sites regarding GST activities whereas CAT activities are enhanced at the freshwater site. In order to reveal more inter-site differences, results will be completed by data provided by other sampling dates and other endpoints. Finally, these results are encouraging for the use of *M. leucophaeata*in ecotoxicology and biomonitoring surveys.

TH131
Effects of a combined chemical and biological stresses on fish immune system.
A. Marchand, J. Porcher, INERIS / INERIS UMRI SEBIO ECOT; S. Betoulle, URCA / UMRI SEBIO; C. TURIES, INERIS / INERIS UMRI SEBIO ECOT; E. Chadili, Ineris UMR-I 02 SEBIO; P. Baudoin, INERIS / INERIS UMRI SEBIO ECOT; A. Bado-Nilles, INERIS
The ecological and chemical deterioration of rivers water quality is a fact. Several studies highlight that a large variety of compounds detected in French rivers could impact physiology of aquatic organisms. The immune system, in particular innate immune response, seems to be very attractive for biomonitoring due to their connection with organism health status. In fact, this innate immune response is a part of the first line defense in the immune system of organisms acting against pathogens without prior exposure to any particular microorganism. Moreover, organism's defenses may be modified by pollutants leading to increase effect of endotoxin. In this context, the stresses induce by chemical (chlorpyrifos) and combined chemical/pathogens (LPS endotoxin) were determined in the three-spined stickleback, *Gasterosteus aculeatus*, after 4 days of exposure. For chlorpyrifos, dissimilar effects were obtained when fish were exposed to chemical stress alone or combined chemical/endotoxin stresses. An increase of the oxidative burst was observed in fish exposed at high doses of chlorpyrifos. Moreover, the injection of LPS increases immune response at low concentration of chlorpyrifos whereas at higher concentration of chlorpyrifos the immune response was lower than control values. Lysosomal membrane integrity was disrupted by the double contamination, at low and high doses of chlorpyrifos. This study shown that chlorpyrifos have hazardous effects on susceptibility of fish immune system to pathogens.

TH132
The effects of nutrient and pesticide mixtures on the Australian midge Chironomus tepperi
M.N. Hoak, CAPIM, The University of Melbourne / Biosciences; S.M. Long, CAPIM / School of Biosciences; V.J. Pettigrove, The University of Melbourne / Zoology
Phosphate is one of the most common forms of nutrient contamination globally and can cause problems when found in high concentrations. It often occurs in mixtures with many different kinds of toxicants, one of the most common being pesticides. Little is known about the impacts of nutrients on the toxicity of pesticides, despite their common co-occurrence. The aim of this study is to identify the impact increasing concentrations of phosphate have on the survival, growth, and protein concentration of the Australian midge *Chironomus tepperi* and whether these levels of phosphate alter their ability to cope with increasing concentrations of the synthetic pyrethroid insecticide permethrin. Sub-lethal concentrations of both phosphate and permethrin were used in a 96-hr sediment exposure on 2nd instar *C. tepperi* larvae and the survival, growth, and protein concentration of the larvae were measured. In two experiments fifteen 2nd-instar larvae were exposed to spiked sediment and water over 96-hrs. For the phosphate exposure, phosphate concentrations of 0, Control (0.5), 10, and 40 mg/L were created and used as the overlying water for clean sediment. For the permethrin/phosphate exposure, normal and high solutions were created with 0.5

(Control) and 40 mg/L of phosphate and used as the overlying water for sediment spiked with permethrin at low, medium, and high concentrations (62, 250, and 2000 μg/kg). The results showed that the phosphate addition increased the protein concentration in the larvae at higher concentrations (p=0.49), but had no effect on survival or growth. In the permethrin/phosphate exposure high concentrations of permethrin reduced survival regardless of phosphate addition (p=.016). However, when exposed to low concentrations of permethrin the addition of high concentrations of phosphate significantly increased the protein concentration found in *C. tepperi* larvae, but did not affect their growth (p=.001). Our results indicate that increased levels of phosphate may protect organisms from the adverse effects of low concentrations of other pollutants.

Identification and prioritisation of hazardous pollutants in the aquatic environment - the role of effect-directed analysis, monitoring and modelling (P)

TH133

Disentangling ecosystem stressors along a river continuum covering a pollution gradient

U.S. McKnight, Technical University of Denmark (DTU) / Environmental Engineering; A.T. Sonne, Danish Technical University / DTU Environment; J.J. Rasmussen, Aarhus University / bioscience; W. Traunspurger, University of Bielefeld / Department of Animal Ecology; S. Höss, Ecossa; P.L. Bjerg, Technical University of Denmark DTU / Environmental Engineering

Environmental pollution is intrinsically linked to the way humans live. Many of the environmental problems we face today have existed for decades; what has changed is our understanding of the key drivers, processes and impacts. In 2009, the reporting by Member States (MS) across the European Union (in 6-yr cycles) on the status of their water bodies found that rivers and transitional waters were often in worse condition than lakes and coastal waters. This is not surprising considering that streams integrate all of the diverse stressors found within a catchment (e.g. contaminated sites; diffuse source pollution; water abstraction). The chemical status of a water body is relatively straightforward to assess, defined in part by environmental quality standards on priority substances and in part by additional regulations imposed by individual MS. However, the biological quality elements used for the classification of ecological status are only loosely defined, leaving MS free to develop their own assessment tools. Although useful for the individual MS, it impedes methodological standardization across different ecoregions, thus contributing to inconsistencies and data gaps across Europe. Moreover, despite the unambiguous importance of benthic habitats for overall ecosystem health, many biological indices tend only to reflect the ecological quality of surface water, rather than of the sedimentary zones where the accumulation of pollutants is often highest. To address this issue, we monitored meiobenthic (i.e. nematodes) and macrobenthic invertebrates along a pollution gradient in order to assess the impact of multiple stressors on a groundwater-fed stream, and thus, to quantify the link between chemical and ecological status. Physical conditions were comparable among sites. The studied stressors included point source pollutants originating from contaminated groundwater and aquaculture, and diffuse source pollutants originating from conventional agriculture and urban areas. The results indicate a change in community composition for both meio- and macrobenthic fauna, pointing towards the presence of a local impact resulting from the discharging contaminated groundwater, which extends downstream along a dilution gradient of the groundwater contaminants. Ecological impacts could be linked to xenobiotic compounds coming from groundwater (both chlorinated solvents and pharmaceuticals), as well as the presence of trace metals (particularly copper and aluminum).

TH134

Surfactants homologues profiling by non-target screening in sediment and Cladophora extract from freshwater river.

H. Byers, L. Krauskopf, M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; M. Schmitt-Jansen, UFZ - Helmholz Ctre Environm. Research / Department of Bioanalytical Ecotoxicology; W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis

Due to the wide use of surfactants, in personal care product, pharmaceutical, pesticides, their presence is rather ubiquitous in the environment. Previous studies have shown that surfactants may be found in the aquatic environment at concentrations, which may be orders of magnitude above other micro-pollutants and result in notably high hazard quotients. Due to their amphiphilic properties surfactants are likely to sorb on surface. Previous work has shown their presence in sediment, but few have been investigating *Cladophora* as potential accumulation compartment. *Cladophora* are often found in nutrient rich river waters downstream of WWTP output, a known emission source of surfactant in the environment. The monitoring of chemicals like surfactants, in these algae will help to estimate the exposure and risks of the respective aquatic ecosystem. In addition, the traditional approach to focus on a few target surfactants for environmental monitoring could underestimate the presence of surfactants in aquatic ecosystems. Indeed, surfactants are often produced together with other homologues having different chain length, these surfactant profiles can as well be found in the environments. Therefore non-target screening of surfactant homologues would bring a better understanding of the fate of surfactant in aquatic ecosystem. In a case study, Holtemme River in Saxony-Anhalt (Germany), which is impacted by WWTP effluents, has been sampled for sediment and *Cladophora*. Non-target screening with a special focus on surfactant homologues was performed on in several compartments, such as sediment and *Cladophora*. The algal toxicity of the environmental fraction was performed too. The method used for this study includes sequential extraction by Pressurized Liquid Extraction, combined with further clean-up steps; the chemical analysis was performed by LC-ESI-LTQ-Orbitrap-MS analysis. Longitudinal profiles of surfactants homologues in the Holtemme River and several of it's tributaries have been identified. Point sources of surfactants have been confirmed hot spots for subsequent in-depth investigations have been identified.

TH135

A non-target screening method for contaminants in fish

F. Yang, Helmholtz Centre for Environmental Research UFZ; B. Deutschmann, RWTH Aachen University / Institute for Environmental Research Biology V; M. Krauss, T. Schulze, W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis

Compared with target analysis, non-target screening provides more comprehensive information on the chemical burden of fish tissues involving potentially pervasive but unknown compounds. In this study, a non-target screening method was developed to detected contaminants in fish muscle. Tissues are lyophilized and then extracted, purified by QuEChERS and subjected to non-target screening in both negative and positive mode with UPLC-Orbitrap-MS. Method development was based on 105 compounds covering a wide range of physiochemical properties and including chemicals that have been found in fish tissue before. The recoveries ranged from 6-167% for all the compounds and 70-110% for most of the compounds. The matrix effects were also in acceptable levels, mostly varying from 80-120%. The method was applied to assess the chemical exposure of contaminants in the fish collected from River Holtemme, Germany. Several contaminants were identified in the fish including naphthalene, benzophenone, fluoranthene, cypermethrin, 4-octylphenol, dibenzylether, carbezole, tonalide and triclosan-methyl. Further quantitative analysis revealed that cypermethrin and 4-octylphenol were the predominant contaminants in the ng/g dry weight range. Moreover, the accumulation patterns of contaminants in the fish identified by the approach were well in accordance with the input of known contamination sources. The preliminary application indicates that the non-target screening method is a promising tool to disclose the chemical exposure and identify the predominant contaminant/s in fish.

TH136

Biomarker response analysis in fish within the SOLUTIONS project - Case study Holtemme

B. Deutschmann, RWTH Aachen University / Department of Ecosystem Analysis ESA; T. Seiler, RWTH Aachen University / Ecosystem Analysis; F. Yang, Helmholtz Centre for Environmental Research UFZ; N. Markert, RWTH Aachen University / Ecosystem Analysis ESA; M. Velki, Josip Juraj Strossmayer University in Osijek, Department of Biology / Department of Ecosystem Analysis ESA; W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis

Close collaboration with several case studies is one of the main advantages in terms of the realization of biomarker response analysis within the 7th EU RTD Framework Programme project SOLUTIONS (Solutions for present and emerging pollutants in land and water resource management). By using the infrastructure of these studies, biomarker monitoring approaches can be performed easily. Under the lead of the Helmholtz-Centre for Environmental Research the small river Holtemme was investigated in an interdisciplinary approach. The stream has its source in the Mountain Harz region (Germany) and flows through a number of small and medium-sized cities in Saxony-Anhalt. Due to its low water-quantity and several anthropogenic point sources the Holtemme is a very valuable model site to assess the impact of pollution induced biomarker responses in aquatic organisms. 10 individuals of brown trout (*Salmo trutta*) were collected at each of 4 different locations including a “natural” reference site. Locations were downstream waste water treatment plants (WWTPs) and one location in a more agriculturally influenced river section. The utilized biomarker battery covered a broad range of proven endpoints which have been employed in several previous studies: genotoxicity in peripheral erythrocytes (micronucleus test), biotransformation enzyme activity (EROD, GST, CES), oxidative stress (TBARS, CAT) and biomarker of exposure to organophosphate and carbamate pesticides (AChE). To reduce time and sample consumption all common cuvette analysis for these endpoints were adapted to 96-well plate assays. For most of the investigated biomarkers significantly elevated/lowered values for the urban and agriculture-affected sampling sites could be demonstrated in comparison to the reference site. However, the results indicated no similar trend for all biomarker responses along the longitudinal profile of the River Holtemme, but the individual biomarkers gave “hot-spots” of response. Correlation analysis with chemical data might help to identify presumed stressors related to the different observed effects.

TH137

Simultaneous determination of PAH metabolites in fish bile by gas chromatography-tandom mass spectrometry

K. Kim, Pusan National University; J. Oh, Pusan National University / Department of Civil and Environmental Engineering

Recently, there have been frequent oil-spills along Korean coastal areas. So many studies have been conducted to assess the marine environment contamination and impacts on the ecosystems. Among the numerous oil originated contaminants, most of the studies have focused on parent pollutants. However, after organisms are exposed to pollutants such as PAHs, xenobiotic enzymes are released in response for oxidation, reduction, hydrolysis and other processes leading to the breaking down of the parent compound to metabolites. The focus of most pollution assessment is often on the parent pollutant not the metabolites though the parent compound has been partially or completely transformed. Therefore, in this study, we aimed to develop an analytical method for PAH metabolites in fish bile samples to enable us to understand PAHs metabolic pathways and their distribution in the marine ecosystem. For this study, ten PAH metabolites were investigated using GC/MS/MS A fast and efficient extraction procedure was developed in order to quantify the ten metabolites of naphthalene, fluorene, phenanthrene and pyrene in fish bile. Detection and identification of the analytes were achieved using gas chromatography coupled with tandem mass spectrometry. Deuterium-labeled hydroxy PAHs were used as an internal standard. The established method includes enzymatic hydrolysis, liquid-liquid extraction and derivatization. The recoveries were obtained from flatfish (79.8%-104.2%), marbled sole (85.7%-106.6%) and rockfish (88.3%-115.8%) in this developed condition.

TH138

Used of fish immune response in environmental risk assessment

A. Bado-Nilles, INERIS; J. Porcher, INERIS / INERIS UMRI SEBIO ECOT

Growing awareness of the value of ecosystems is linked with the increasing demand by citizens and environmental organizations for cleaner rivers and lakes, groundwater and coastal beaches. This citizens demand is one of the main reasons why the Commission has made water protection one of its priorities. This explains the restructuring process of the Water Framework Directive (WFD 2000/60/EC) which concerns the general protection of aquatic ecology, specific protection of unique and valuable habitats, protection of drinking water resources, and protection of bathing water. Two elements are integrated in the ecological protection of surface waters: the "good ecological status" and the "good chemical status". Thus, the environmental objectives concern long-term sustainable water management based on a high level of protection of the aquatic environment and the introduction of the principle of preventing any further deterioration of the ecological and chemical status. In fact, the introduction of several environmental pollutants in freshwaters induces adverse effects in aquatic ecosystems by the disturbance of several physiological processes of aquatic organisms. This modification of the ecosystem could be avoided by increasing our knowledge on the chemical injuries induced on the main physiological functions, such as reproduction, maintenance, survival and behavior. In this way, we want to demonstrate the interest of fish immune response in environmental risk assessment using different river samplings.

TH139

Miniaturization of the salmonella/microsome assay in microsuspension

J.R. Zwarg, School of Technology, UNICAMP; D. Morales, School of Technology, UNICAMP / LEAL Laboratory of Ecotoxicology and Environmental Microbiology; G. Umbuzeiro, SCHOOL OF TECHNOLOGY -UNICAMP / LEAL

The Salmonella/microsome assay is the most used mutagenicity test both for evaluation of chemicals and environmental samples. There are several versions of protocols available in the literature. Miniaturization of toxicological tests has been a tendency in compliance with the concept of the 3Rs (Replacement, Reduction and Refinement). MPF is a successful miniaturized version of the Salmonella/microsome assay, uses liquid medium and has a limited window of response. When quantification of the mutagenic response is important and strains with very different spontaneous reversion rates are used the assays has some limitations. Recently a protocol that uses 24 well agar microplates was developed and similar results were obtained when compared to the regular Ames test (plate incorporation version). The objective of this study was to miniaturize of the microsuspension Salmonella/microsome assay using agar microplates under the concept of the 3R and different strains with spontaneous revertants rates (low, TA1538, medium, TA98 and high, YG1041). Following the same procedure of the test Salmonella/microsome in microsuspension. Overnight cultures are concentrated 5-fold by centrifugation and resuspended in 0.015M sodium phosphate buffer. A volume of 50μL of cell suspension and 2μL of the sample are added in a tube and mix, then 13μL of this mixture are transferred for each tube test containing 12,5μL of 0.015M sodium phosphate buffer or S9 mix and are incubated at 37ºC for 90 min. To this new mixture, 500μL of molten agar are added and 200μL are poured into each well containing minimal agar. Colonies were counted after 66h incubation at 37ºC. Results were expressed as minimum effective concentration (MEC2), which is the concentration that provides the double of the spontaneous revertant rate. We are presenting data for TA1538 and TA98. Experiments with YG1041 are still being perfomed. Both protocols MPA and Microsuspension provided similar sensitivity for the strains analyzed so far. The MPA procedure is less laborious and uses less sample, materials and reagents. MPA procedure seems to be a promising tool specially to test environmental samples for mutagenic activity when quantity of sample is usually a limiting factor.

TH140

Chemical and effect screening of sediments in European estuaries: River basin specific pollution versus Europe-wide priorities

R. Massei, Helmholtz Centre for Environmental Research UFZ; H. Wolschke, Helmholtz Centre Geesthacht; M. Bitsch, Helmholtz Center for Environmental Research / Effect Directed Analysis; L. Schinkel, ETH Zürich/Empa / Laboratory for Advanced Analytical Technologies; T. Schulze, M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; S. Scholz, Helmholtz Centre for Environmental Research / Department of Bioanalytical Ecotoxicology; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis; W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis

In the frame of the Water Framework Directive (WFD) a good chemical status needs to be achieved in European rivers. The rivers are subjected to continuous discharge of various organic pollutants due to diffused and point sources (i.e. wastewater treatment effluents, agriculture and surface run-off). However, there is a general lack of knowledge regarding their occurrence and potential ecologic effects in different river basins. Disparate regulations of different countries and emission sources can also result in unpredictable scenarios in different European river basins. Therefore, a systematic monitoring of many emerging pollutants is not routinely applied and their environmental fate and ecotoxicological impact is still unknown. In order to assess the contamination patterns and the drivers of site- or estuary-specific effect responses, sediments samples of the estuaries of eight European river basins were collected. Sediments were selected due to their well-known role as a sink for hydrophobic persistent organic pollutants such as PAHs, PCBs or brominated flame retardants. However, in recent studies, it was suggested that also more polar compounds accumulate in sediments and significantly contribute to the general toxicity. The sediments were subjected to targeted chemical screening with high resolution LC- and GC-Orbitrap-MSMS of polar and non-polar organic compounds including for example classical POPs, pharmaceuticals, personal care products, surfactants, pesticides and biocides. Effect patterns were recorded using *Danio rerio* embryos applying a set of developmental endpoints together with specific biomarkers of toxicity including acetylcholine esterase activity, cyp1a and aromatase and behavioral assays such as locomotor response. Passive dosing was applied in order to simulate the exposure of fish embryos to the sediments. Preliminary chemical analysis of 15 pyrethroids and 19 PAHs show that there is a different distribution in different river basins. Also the bioassay results showed different toxicity patterns according to the sampling area. This approach will allow for multivariate analysis of contamination and effect patterns in order to group sampling sites and river basins and to identify the drivers of site- or estuary-specific response and thus supports the identification of River Basin Specific Pollutants.

TH141

Determination of Pesticide residues in sediment samples from Büyük Menderes River and Possible Risks for agriculture

a. gavcar, Adnan Menderes University; M. Yalçın, Adnan Menderes University / Faculty of Agriculture; C. Turgut, ADU

Pesticides are widely used because of the intensive agriculture. Runoff from areas treated with pesticides can pollute water. Pesticide residues in surface water can harm plants, animals and also ground water. Great Meandros River is very important for irrigation of surrounding fields in valley and also water system is used to deliver of river water to far away for ensuring irrigation in many crops. Meandros river was diveded in to 8 part in the same distance and 8 sediment samples were collected along the river. The samples were analysed by GC/MS-MS and LC/MS-MS. The most prevalent pesticides were detected 4,4 DDE, Fluvalinate, Formathion, Fenvalerate, Carbofuran and Pyrimethanil. A long term contamination of this pesticides could be expected by using them as irrigation water to the food web.

TH142

Effect-directed analysis (EDA) of Danube River water samples receiving untreated municipal wastewater from Novi Sad, Serbia

M.A. Hashmi, Helmholtz Centre for Environmental Research-UFZ / EffectDirected Analysis; M. Koenig, Helmholtz Centre for Environmental Research UFZ / Department of Bioanalytical Ecotoxicology; P. Neale, The University of Queensland / National Research Centre for Environmental Toxicology Entox; B.I. Escher, Helmholtz Centre for Environmental Research UFZ / Cell Toxicology; M. Krauss, T. Schulze, Helmholtz centre for environmental research - UFZ / EffectDirected Analysis; H. Hollert, RWTH

Aachen University / Department of Ecosystem Analysis; W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis
The presence of endocrine disrupting chemicals (EDCs) in municipal wastewater has raised great concern regarding environmental health of aquatic ecosystem. Biologically active substances may cause harmful effects to human health and environment due to their potential to disrupt the endocrine system. The city of Novi Sad is one of the hot spots of pollution in the Danube River emitting untreated municipal wastewater into the river. The objective of this study is to identify EDCs and compounds causing oxidative stress responses in Danube river water influenced by Novi Sad wastewater through effect-directed analysis (EDA). Water samples from Danube River were extracted on-site using large volume solid phase extraction (LVSPE) into three different fractions i.e., neutral, acidic & basic with chromabond HRX sorbent (hydrophobic polystyrene-divinylbenzene copolymer). These extracts were pre-screened on GeneBLAzer bioassays (mammalian cancer cell lines) for agonistic and antagonistic hormonal activity for three nuclear hormone receptors (estrogen, androgen, progesterone) and one for adaptive stress response i.e., oxidative stress. Preliminary results showed highest estrogenic, antiandrogenic and oxidative stress potencies in neutral extract, which was selected for effect-directed analysis of chemicals causing these effects. Reversed phase-high performance liquid chromatography (RP-HPLC) fractionation was carried out with gradient elution by using C-18 silica based column (Macherey-nagel Nucleodur Gravity) with mobile phase methanol:water (50:50) with 0.1% formic acid. Two minute fractions (from 4-64 minutes) were collected (total 30 fractions) and reduced to dryness by an approach combining evaporation with solid phase extraction (SPE) on HRX. Biological analysis of these 30 fractions on GeneBLAzer identified several active fractions which are addressed with targeted and/or non-targeted analysis using LC-MS/MS.

TH143

Identification and Ecological risk assessment for genotoxic compounds in the Danube River

Y. Shao, B. Deutschmann, RWTH Aachen University / Department of Ecosystem Analysis ESA; T. Schulze, W. Brack, Helmholtz Centre for Environmental Research UFZ / EffectDirected Analysis; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis; T. Seiler, RWTH Aachen University / Ecosystem Analysis

One of the major challenges that environmental toxicologists and risk assessors are facing is the identification of exact toxicants in the complex exposure scenarios that are typical for many environments which we wish to protect. For that purpose, a linkage of effect data and hazardous compounds is required. In this study, bioassays, software simulation and chemical analysis were integrated to evaluate the potential ecological risk in the Danube River. The results indicated that samples from all three hotspots that were confirmed by fish embryo test (FET) induced significant genotoxic effects. According to the simulation of QSAR Toolbox and ChemProp, pesticides and PAHs were predicted to be the most genotoxic chemicals. Similarly, chemical analysis demonstrated that pesticide, especially 2,4-dinitrophenol, is the main genotoxicant in the Danube River. Ecological risk assessment by risk-quotient (RQ) method illustrated that 2,4-dinitrophenol caused medium level risk in the Danube River.

TH144

A snow/firn two-century record of polycyclic aromatic hydrocarbons (PAHs) and polychlorobiphenyls (PCBs) at GV7 (Antarctica)

s. giannarelli, University of Pisa / Chemistry and Industrial Chemistry; R. Fuoco, S. Francesconi, University of Pisa / Dept of Chemistry and Industrial Chemistry

A two-century record of fourteen polycyclic aromatic hydrocarbons (PAHs) and seven polychlorobiphenyls\n(PCBs) was obtained from two snow/firn cores gathered at GV7 (Antarctica) in order to assess the contribution\nof human activities to global environmental pollution. The total concentrations of ΣPAH14 and ΣPCB7\nwere 1.2 ng/l and 0.09 ng/l in the deepest firn sample analyzed, and 3.4 ng/l and 0.22 ng/l in surface snow samples\ndeposited over the last fewyears, respectively. Our data highlighted the presence of PAH maxima in the concentration\ndepth profile, which correlated with non-sea salt sulphatemaxima associated with the major known\nvolcanic eruptions in the period 1800–1930. Between 1930 and 2002, PAHs showed an overall 50% increase, with a slope of about 0.013 ng l^{-1} $year^{-1}$. This\ncan be predominantly attributed to the emission of incomplete combustion processes of organic matter related\nto anthropogenic activities. PCBs show a much higher increase (+200%)with a slope of 0.0034 ng l^{-1} $year^{-1}$ in\na very limited period (1930–1980) which is almost totally due to the massive industrial production and use of\nPCBs, here named “industrial PCB excess”. The slight tendency of PCBs to a constant level from 1980 to 2012\nmight be attributed to the reduction in the industrial production of PCBs and the restricted use only in totally\nenclosed systems which started in many countries in the late 1970s.

TH145

Prioritisation of Pharmaceuticals in the Natural Environment in Kazakhstan

B. Aubakirova, L.N. Gumilyov Eurasian National University / Management and Engineering in environmental protection; A. Boxall, University of York / Environment Department; R. Beisenova, LN Gumilyov Eurasian National University / Management and Engineering in environmental protection

Pharmaceuticals are readily available in Kazakhstan with most of them being freely available for purchase over the counter. Wastewater treatment systems in Kazakhstan are also old and employ old technologies so the treatment may not be as effective as in western countries. Consequently, emissions of pharmaceuticals to the natural environment in Kazakhstan are expected to be high and impacts could be greater than elsewhere in the World. However, unlike contaminants such as metals, oil and rocket fuels, which have been heavily studied in Kazakhstan, there are no data on the concentrations and impacts of these substances in rivers and streams in the country. In this poster, we present a desk-based study to prioritise active pharmaceutical ingredients of most concern in surface waters in Kazakhstan. Initially data were collected on the number of products and active ingredients for different therapeutic classes in use in Kazakhstan and on the typical doses and treatment durations. These data were then used alongside simple exposure modelling approaches to estimate concentrations of active ingredients (>500 active pharmaceutical ingredients from around 1800 products) in surface waters in Kazakhstan. For each of the active ingredients, the potential hazard to aquatic organisms was predicted based on human pharmacology data and also using quantitative structure-activity relationships. Risk quotients were then calculated for each pharmaceutical based on the exposure and hazard predictions and the substances ranked in order of risk quotient. In the future, experimental studies are planned in Astana, the capital of Kazakhstan, to characterise the concentrations of the top priority compounds in surface waters and to monitor whether impacts of these could be occurring in reality.

TH146

An integrated approach to assessing exposure and ecotoxicological impacts in the State of Qatar

C.S. Warren, S. Saeed, ExxonMobil Research Qatar / Environment and Water Reuse Program; S. Prakash, V. Kolluru, Environmental Resources Management

Exposure science and ecological risk assessment continues to develop and evolve in the State of Qatar. Efforts have been taken to utilize appropriate tools and methodologies developed in North America, Europe as well as other relevant hot and arid countries. In many cases, however, the extreme environmental conditions (e.g., high water temperature and salinity) and differing ecosystem structures (e.g., warm water species such as corals) require adaptation of the typical approaches and tools. At EMRQ we are developing an integrated approach to assess discharges, fate, exposure and ecotoxicological impacts in the marine environment. Our initial focus has been on the Liquefied Natural Gas (LNG) industry which is important to Qatar and other global regions; and increasingly so for North America and Europe. We have worked closely with our industry partners to robustly quantify discharges and model transport/fate using a spatially and temporally resolved hydrodynamic model combined with laboratory-based data. We also incorporate measured field data for evaluation of these tools and to assess ecological impacts. In the laboratory we have developed ecotoxicology protocols for reference species applicable to Qatari waters as well as dose-response relationships across various trophic levels and key contaminants. Current efforts include the development of an EcoRisk modeling framework which ties together these multiple components and environmental stressors into a tool that can be used by industry and government to assess ecological risk related to current discharge and exposure scenarios and also for future predictive and planning purposes.

TH147

Incorporating diffuse emissions in a load-impact based prioritization approach for metals

P. Van Sprang, ARCHE; F. Van Assche, IZA; H. Waeterschoot, Eurometaux

In an effort to enhance public access to information, to examine progress in reducing emissions and, possibly, to help setting priorities for reducing emissions that may cause risk to man and environment, national and regional Pollutant Release and Transfer Registers (PRTRs) have been established. Currently, a series of metals are included in the reporting requirements that in first instance focus on point source and fugitive emissions at industrial sites. More recently the OECD debated about extending the PRTR schemes to include product and non-point source releases in order to make the pollutant registers possibly more relevant for risk prioritization and regional risk assessment. Indeed, PRTR registers are increasingly used for risk priority setting schemes under chemical management programs to ensure a more risk based rather than a hazard based prioritization. Currently, a main issue is that substances registers only include emissions (loads) making comparisons for prioritization less relevant if no correction is applied for impact (toxicity) potential. This poster will provide the outcome of a large exercise conducted by the metals sector (including Cd, Co, Cu, Mo, Ni, Pb, Sb, V and Zn) in the EU.. The metal loads at EU scale of non-point diffuse sources from products and other sources were assessed using up to date information and methodologies. Load-impact ratios were calculated as the ratio between the loads (t/y) and the metal specific chronic environmental toxicity reference values (e.g. HC_5). The relevancy of these load-impact results for risk-based prioritization approach and will be further discussed.

TH148

Degradation of Acetamiprid by esterase from aqueous solution
M. Yalçın, Adnan Menderes University / Faculty of Agriculture; C. Turgut, ADU
Esterases are a group of enzymes which are the most important in the metabolism of xenobiotics including many pesticides. They protect the target site (acetylcholin esterase) by catalyzing the hydrolysis of pesticides.Acetamiprid is an systemic insecticide that is used to control many pests (e.g. Hemiptera, especially aphids) by soil and foliar application on a wide range of crops. The residue of acetamiprid is a big issue in many crops and countries. The aim of this study was to remove Acetamiprid in aqueous solution by addition of esterase enzyme. The process of acetamiprid removal from aqueous solution using esterase enzyme has been analyzed. Experiments were carried out at different time, different dose and pH to determine the optimum removing conditions. Analyses of acetamiprid residues conducted by LC/MS/MS. The performance of acetamiprid removal was found to be highly dependents on these conditions. Maximum removal was observed by esterase when compared by lipase and cellulase. Moreover our results will create opportunities for engineering degradative enzymes but more concentrations and mixture pesticides should be tested for further studies.

Identifying and regulating PBT and vPvB chemicals: Requirements,challenges and policy implications (P)

TH149
Bioaccumulation and PBT/vPvB assessment of organic substances: the inherent and unavoidable flaws in the current REACH approach
O. Warwick, Peter Fisk Associates Limited; P.R. Fisk, Saxon House
Measurement of persistence, bioaccumulation and toxicity (PBT) properties is essential for identification of substances of very high concern. The assessment of the B criterion has challenges since it is currently based on relative rather than absolute metrics. This review focusses on the inherent flaws in some of the regulatory metrics for B, which are rooted in the low relevance of laboratory studies to environmental fate. Such a criticism is much less applicable to the measures of persistence and toxicity. Laboratory studies of bioconcentration/magnification factor (BCF and BMF), investigate minimal aspects of real environmental behaviour i.e. only uptake and elimination in very simple studies. More fundamentally, it cannot be avoided that these metrics depend strongly on exposure concentrations (e.g. high exposure in the diet can overwhelm the ability of the organism to depurate and confound meaningful measurements). The expression of, for example, BCF as a ratio of concentrations without reference to exposure, generates an illusion of steady state and a fixed metric. However, BCF considered as a ratio of *rate constants* is more useful. Therefore, the current system is internally flawed because a supposedly *intrinsic* property actually depends on exposure concentration, both in the lab and the environment. In reality, it is necessary to have a proper understanding of exposure route when considering uptake in the food chain. Yet the regulation is expressed without reference to exposure. Various authors have suggested metrics that are more robust measures of ‘B’ than BCF or BMF; only those which refer to rate are really useful. As far as possible, elimination rates should be based on environmentally-relevant exposures. What is the consequence of the flawed understanding of bioaccumulation metrics? Paradoxically it leads to the inconsistency that exposure has to be discussed when determining the hazardous properties! A properly-functioning regulation is needed because the regulatory consequences are serious: rigorous control of exposure and possible withdrawal from the market. The anomalies are particularly severe for ‘vB’. Some ways forward are suggested, based on meaningful measurements of elimination rates under relevant conditions; this would put B on a more solid basis, more consistent with P and T which have meaningful absolute units.

TH151
Monitoring, but for what? - Designing contaminant monitoring on a National scale.
E. Farmen, M.V. Dimmen, B. Nordbø, S. Andersen, A. Sundbye, Norwegian Environment Agency
Whereas PBT and vPvB focused contaminant monitoring may serve to collect important field data for regulation of chemicals, the purpose of environmental monitoring is commonly also to inform about the state of the environment. The environmental monitoring run by the Norwegian Environment Agency are currently trying to do both, but are we doing it right? Traditionally, National contaminant monitoring programmes in Norway were designed to assess time trends in order to detect alarming levels and changes in levels of contaminants. In recent years, increased effort has been put in addressing how contaminants biomagnify in both aquatic and terrestrial Norwegian food webs. Such measurements potentially inform regulators on real world occurrence and fate of chemicals, and have shown to be a useful correction to lab-based measurements. Although valuable data already have been generated with this approach through Norwegian monitoring programmes, food webs fit for purpose has proven to be far from off-the-shelf. Whereas the model for fresh water biomagnification appears to work well, tools for marine and terrestrial food chains are more challenging. Moreover, other requirements for contaminant monitoring, such as implementing mixture toxicity risk assessment, evaluation of biological effect, and an ever-changing list of emerging contaminants for monitoring, leaves design of National monitoring a perpetual task. In the end, the question for regulators is therefore to what extent National contaminant monitoring should be focusing on emerging PBT and vPvB chemicals, compared to assessing the state of the environment.

TH152
Chemical policies, regulations and conventions in protection of European waters - Overlaps and gaps
J. Lexén, T. Skårman, E. Brorström-Lundén, M. Rahmberg, T. Rydberg, IVL Swedish Environmental Research Institute; J. Munthe, IVL Swedish Environmental Research Institute Ltd
Several policy instruments (Regulations, Directives and Conventions), which regulate emissions of chemicals and use of chemicals in preparations and articles for reducing risks to the environment and human health by chemical pollution, have been reviewed with the aim to investigate how benefits can be gained by increased coordination, harmonisation and cooperation: EU Regulations - REACH, Plant Protections Products Regulation, Biocidal Products Regulation; EU Directives - Groundwater Directive, Marine Strategy Framework Directive, Drinking Water Directive, Urban Wastewater Treatment Directive, Sewage Sludge Directive, Industrial Emissions Directive, RoHS Directive, Toy Safety Directive; Multilateral environmental agreements - Stockholm Convention, CLRTAP, PRTR Theevaluation of potentials for synergies as well as risk for conflicts is carried out by a literature review, based mainly on information from the web sites of the issuers and from the legal documents and conventions, comparing how the following key aspects in WFD are treated in the other studied instruments: General characteristics: a) Scope: inland surface waters, transitional waters, coastal waters and groundwater; b) Reporting level: river basin; c) Substances Implementation: d) Characterisation of water bodies; e) Identification of pressures and impacts (emissions from point sources, emissions from diffusiive sources, establish inventories of emissions, discharges and losses); f) Monitoring programmes (concentrations); g) Status assessment of water bodies (Ecological status, Chemical status, Environmental Quality Standards; h) Programme of mesures; i) Reporting (river basin management plans) Early results indicate the potential for increased cooperation and coordination between e.g. WFD and REACH, for the safe management of chemicals, such as better sharing of information between the different instruments. Further analysis will address, e.g., procedures for including new substances, efficiency in implementing restrictions or bans, sharing of compiled information on occurrence, effects, properties and abatement options, specific sectors of society where chemical legislation needs strengthening. Future instruments development will be discussed to protect European waters against chemicals of emerging concerns and mixture effects– an innovative legislative framework also embracing novel risk assessment frameworks such as chemical footprints and planetary boundaries for chemicals.

TH153
OECD Test No. 309 (Aerobic Mineralisation in Surface Water) not applicable for a persistence assessment of strong adsorbing plant protection products with low water solubility
J. Hassink, B. Jene, BASF SE / Environmental Fate; D. Ebert, BASF SE
The OECD 309 study (Aerobic Mineralisation in Surface Water) is a new data requirement under EU regulation 1107/2009 for plant protection products, where compounds are incubated in an isolated natural water in glass vessels for 60 days with no contact to sediment. All experiences gained so far confirm that hydrolytically stable compounds will not degrade in this study because microbiological activity under thus artificial conditions is not sufficient to mediate significant degradation. The majority of the substances are required to be hydrolytically stable to be used by the farmer in spray application. In contrast to the OECD 309 study, the water/sediment study (OECD 308) is designed to provide at least a minimum of microbial diversity as existent in natural water bodies. It represents the most relevant worst-case exposure scenario of plant protection products, i.e. the exposure via spray drift, run-off or drainage of a small freshwater body with sediment at the edge of an agricultural field. The OECD 309 study might provide additional information for the risk assessment of a water soluble compound in coastal or oceanic water compartments but it is not appropriate to determine P-criteria for strong adsorbing substances with low water solubility by this study type, which is agreed by SANCO and ECHA guidance. The whole system DT_{50} of the OECD 308 is the only reliably estimated degradation half-life in a water containing system and therefore more suitable. Furthermore, photolytical degradation of a compound should be considered when relevant. As an example for low soluble and strong adsorbing substance, experimental data for the herbicide pendimethalin are outlined and discussed. Pendimethalin is hydrolytically stable and under the artificial conditions of the OECD 309 study (no light, no sediment) would exceed the P-trigger of 40 days for freshwater. However, in addition to the fast degradation in water by photolysis (DT_{50} 3.5 d), pendimethalin partitions within a few hours from the water into the sediment where it is rapidly degraded. Therefore, sediment is the only relevant compartment for pendimethalin in water/sediment bodies to be considered for the P assessment. The total system DT_{50} from water-sediment studies of 19.7 days is far below the P-criterion of 120 d for sediment. Aquatic mesocosm studies with

pristine sediment confirm the rapid partition of pendimethalin into sediment and its fast degradation.

Standards - an essential link between environmental science and regulation (P)

TH154

The Validation of Analytical Methods used in Ecotoxicological Studies

I. Pedall, A. Rastall, A. Sagner, M. Faupel, RIFCON GmbH, Goldbeckstr 13, 69493 Hirschberg, Germany

The validation of analytical methods used in support of ecotoxicological studies has become a vitally important aspect of the registration process for plant protection products. The validation and reporting of analytical methods used to determine pesticide concentrations in ecotoxicological studies conducted for registration purposes are currently regulated by the SANCO/3029/99 rev 4. guidelines. These guidelines have been applicable under Dir 91/414/EC since revision 4 of SANCO/3029/99 was issued in July 2000. However, because directives such as this are generally not legally binding, in the past the guidelines were often either only partially followed or simply overlooked. When Regulation (EC) No. 1107/2009 came into force in 2011, adherence to the SANCO/3029/99 rev 4. guidelines became obligatory. This has resulted in serious implications for the registration process because ecotoxicological studies that had previously been accepted may well now be rejected on the basis of inadequate analytical methodology or incomplete analytical data. This is evidenced by the recent rejection of a number of residue studies by the authorities on the grounds of inadequate analytical methodology and/or data. It is therefore likely that ecotoxicological studies that fail to meet the analytical criteria required by SANCO/3029/99 rev 4. may not be accepted anymore. It is the purpose of this poster to give an overview of current requirements for analytical methods used in support of ecotoxicological studies. We also provide an example of a checklist that can be used to evaluate analytical methods according to SANCO/3029/99 rev 4. Simple tools such as this can be used to elucidate the potentially complex and time-consuming process of assessing the validity of analytical methods used in ecotoxicological studies.

TH155

Normalizing Data to the Control Creates Large Errors

J.W. Green, DuPont / Applied Statistics Group

A technique common in the analysis of some ecotoxicity studies is to normalize data in treatment groups to the control. In the case of quantal data (e.g., mortality, emergence, hatching), the purpose is to adjust mortality data for background incidence and a method for doing this dates from 1925 called Abbott's formula. It has been known since at least 1985 that Abbott's formula can give biased results. Better ways to take background mortality into account have been known for several decades and software is widely available to carry out these alternative methods. This same idea has also been used for continuous responses, where the object is to estimate the concentration at which a specified percent effect relative to the control mean response occurs. The primary purpose in normalizing a continuous response to the control is to modify the data so that a probit analysis (which assumes quantal data) software package can be used. Good models are well known that do not require such data manipulation. It will be proved not only is the analysis of normalized data theoretically unsound and unnecessary, but can produce estimates as much as 6X too large or too small in several types of guideline studies while other readily available approaches provide accurate estimates. Theoretical problems with normalized data are first made clear. Second, data from fish early life stage, non-target plant, and fish sexual development studies are analyzed using probit models fit to normalized data and more appropriate models to indicate the difference in both ECx point and interval estimates. Third, Monte Carlo simulation studies based on experimental designs, variability and dose-response shapes typical of these studies are used to develop distributions for ECx estimates from these models. In the simulation studies, the true ECx is known, so these distributions can reveal the quality of estimates to be expected from the different modeling approaches. Both quantal and continuous data are considered Readily available software allows the use of statistically valid regression models to analyze quantal and continuous data arising from ecotoxicity studies. Analysis of normalized responses is unreliable, with both under- and over-estimation of ECx values by large factors occuring with little way to determine in a particular study that whether such mis-estimation has occurred.

TH156

COMPARISON OF NOEC VALUES TO EC10/EC20 VALUES, INCLUDING CONFIDENCE INTERVALS, IN AQUATIC AND TERRESTRIAL ECOTOXICOLOGICAL RISK ASSESSMENT

F. Galimberti, International Centre for Pesticides and Health Risk Prevention; F. Marchetto, ICPS; L. Menaballi, S. Ullucci, G. Azimonti, International Centre for Pesticides and Health Risk Prevention; A. Moretto, State University of Milano; W. de Boer, H. van der Voet, Alterra Wageningen University and Research Centre

Ecotoxicological studies performed for the authorization of plant protection products (PPP) usually result in the reporting of endpoint values in terms of effect concentration (EC) affecting a percentage x of test organisms or where a x percentage of an effect is observed (EC_x). The new Regulation (EC) No. 1107/2009 for the authorization of PPPs and the related data requirements provide that ecotoxicological endpoint data from chronic or long-term studies submitted by the Applicant are reported as EC_{10} or EC_{20} values together with the NOEC. NOEC values have been criticized since their values strongly depends on the experimental study design, whereas EC_x values take into account the whole concentration-response curve and are therefore considered more appropriate. The aim of the project is to investigate the comparability of the EC_x approach to the current NOEC approach on a larger data sets in view of the new Regulation requirements. Ecotoxicological data gathered from 70 active substances' approval dossiers were collected and stored into a MS Access database. All the extracted ecotoxicological data were analyzed in order to derive NOEC and calculate EC_{10}, EC_{20}, EC_{50} with confidence intervals, using statistical models from the exponential and Hill families for continuous data, and logistic, log-logistic and complementary log-log models for quantal data. The optimal model was selected based on likelihood ratio tests and the Akaike Information Criterion. EC_x/NOEC ratio distributions were calculated considering the whole set of data and model outputs; data were grouped in different categories to remark any differences in the EC_x/NOEC ratio distributions.

TH157

Robust data analysis to derive 17β-estradiol equivalent concentrations in in vitro bioassays

E. Simon, Centre Ecotox / Aquatic Ecotoxicology; C. Kienle; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; E. Vermeirssen, Oekotoxzentrum Eawag-EPFL / Aquatic Ecotoxicology

Several different reporter gene assays that assess the activition of the estrogen receptor are currently being developed as ISO standards. Data analysis of these bioassay results is not a trivial issue and requires consideration to allow for comparable results between different assays or for the same assay but between laboratories.Typically the assays generate sigmoidal dose-response curves when a reference compound (or positive control, PC) or an environmental sample is applied in increasing concentration. Subsequently, dose-response curves of the reference and sample are used to derive equivalent concentrations for the sample. However, curves generated for the samples are often not parallel to those of the reference, or do not achieve minima or maxima values that are similar to the reference. Non-parallel dose-response curves may occur when the compounds in the sample are different from the standard, when antagonists are present in the sample, or when sample matrix interferes with induction in the assay. Maximum induction values may not be reached because of low activity of the sample, sample solubility problems or cytotoxicity. Low activity may be expected, for example, for surface and/or drinking waters. In these cases the type of data analysis that is applied will influence the equivalent concentrations that are derived. This makes the comparison of studies conducted in different laboratories challenging. To circumvent these problems we suggest using the 10% effect level interpolation ("PC10 approach") for *in vitro* data analysis. First, all data are normalized, where 0% refers to the response in the solvent control and 100% is the maximum response fitted for the reference dose-response curve. Then, the 10% effect level of the sample is interpolated from the reference dose-response curve and the 17β-estradiol equivalent (EEQ) concentration of the sample is determined. The requirements to apply the PC10 approach are: an effect level in the sample that is larger than 10%, or the ability to extrapolate the modelled sample response above the 10% effect level a limit of quantification (LOQ) that is below the 10% effect level. To discuss these specific aspects, we applied various calculation methods and show graphical examples of environmental samples that were assessed for estrogenic activity using different bioassays. The "PC10 strategy" appears to provide a harmonized solution for analysing *in vitro* screening data and a standardised data reporting practice.

TH158

Standards for specific in vitro assays - requirements for their implementation in regulatory frameworks

S. Buchinger, Federal Institute of Hydrology / Department G Biochemistry Ecotoxicology; E. Vermeirssen, Oekotoxzentrum Eawag-EPFL / Aquatic Ecotoxicology; G. Reifferscheid, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology

Specific in *vitro assays* allow the assessment of the toxicological mode of action of a compound or the assessment of the toxic potential of an environmental sample. In recent decades, *in vitro* assays in ecotoxicology made a lot of progress because of their advantages such as rapidness, reproducibility, cost-effectiveness and their capability for high-troughput and automation. Although they are more and more accepted as alternative methods for animal testing up to now they are not widely implemented in regulatory frameworks. Still unresolved questions such as suitable mathematical methods for the derivation of effect-equivalence concentrations might hamper their broader use in regulatory frameworks for the aquatic environment. Effect-equivalence concentrations are used to express e.g. dioxin-like activity or estrogenic activity of a given sample as a concentration of a reference compound inducing the same effect-level in the assay. To compare different mathematical approaches for the calculation of effect-equivalent concentrations a set of standard conmpounds with known estrogenic activity were tested in several defined dilutions with the yeast estrogen screen (YES) – a bioassay that is currently being developed as an ISO standard. The selected compounds show specific concentration-response-relationships with e.g. different slopes. The assessment of the various methods for the derivation of equivalence concentrations is based on the assumption that e.g. a 1 to 2 dilution of a given sample should result in a bisected euqivalent concentration after testing with the YES. In case of the non-linear interpolation, a common approach for the calculation of equivalence concentrations, the calculated equivalence concentration depended on the maximal iso-NP-concentration tested in the YES. If a maximal concentration of 500 µl/l iso-NP is tested the calculated EEQ is about 60 ng/l. If the same solution is diluted 1 to 2 and tested again, the resulting EEQ is about 50 ng/l – the apparent EEQ of the undiluted original sample would then be 100 ng/l. The derived EEQ increases with dilution of the iso-NP. The same data will be assessed by several approaches under discussion for the derivation of the EEQ aiming to contribute to the development of a guideline for the derivation of effect-equivalence-concentrations.

TH159

Derivation of Environmental Quality Standards for biota using reliable bioaccumulation data

A. AMARA, M. DALLET, INERIS; S. ANDRES, INERIS / Toxicological Ecotoxicological Assessment of chemical Substances

The Water Framework Directive (2000/60/EC), or WFD, sets the strategy against the chemical pollution of surface water bodies. The evaluation of the chemical status allows parallel with the evaluation of the ecological status, to determine the overall quality of a water body. The environmental quality standards (EQS) are tools used to assess the chemical status of water bodies. Daughter directive (2013/39/EU) considers that EQS must be established in the matrix of the aquatic environment (water, sediment or biota) where a substance is likely to be found and where its concentration is most likely to be measurable. Some substances pose a significant risk through indirect toxicity (i.e. secondary poisoning resulting from food-chain transfer) and their analysis is more feasible in other environmental matrices, such as biota, then a biota standard may be required alongside, or instead of, the water column EQS. This work aims to derive quality standards applicable in biota equivalent to EQS for four dangerous and priority classified substances by the WFD (tributyltin, diethylhexylphthalate, short chains chloralkanes (C10-13) and pentachlorobenzene). Quality standards were derived using bioaccumulation factors. All retrieved literature was evaluated with respect to its relevance and reliability according to the TGD-EQS. Composition and completeness of the marine and freshwater food-chains are evaluated and only reliable and relevant data are considered valid for use in setting a quality standard. According to the matrix of the EQS, the principle of this deriving approach is based on: a conversion of the EQS from water to biota using bioaccumulation factors for each trophic level, or a conversion between different trophic levels (biota) directly by using the biomagnification factor if the substance is biomagnified, or by performing an intermediate conversion into the water if the substance is not biomagnified. Based on this principle, a general methodology for biota standards derivation is proposed. It seeks to determine, using a decision diagram, the best approach to convert a biota standard taking into account the availability of reliable bioaccumulation data. This methodology for deriving biota standards need to be validated for other substances in the context of monitoring of aquatic environments.

TH160

In flow cytometry, does results harmonization requires the same equipment? Case of cell viability

D. RIOULT, UMRI 02 INERIS-URCA-ULH SEBIO / MOBICYTE flow cytometry core facility; A. Bado-Nilles, INERIS; A. Serpentini, Universite Caen Normandie / UMR BOREA Biologie des Organismes et des Ecosystèmes Aquatiques MNHN UPMC UCBN CNRS IRD; B. Gagnaire, IRSN / laboratoire décotoxicologie des radionucléides; M. Auffret, Universite de Bretagne Occidentale / LEMAR; P. Brousseau, INRS Institut ArmandFrappier; F. Le Foll, SEBIO UNIVERSITY OF LE HAVRE; S. Betoulle, URCA / UMRI SEBIO

Flow cytometry allow analysis of cellular parameters or functions in order to obtain statistical dimension both populational and individual. University of Reims Champagne Ardennes and INERIS, have set up a mobile environmental flow cytometry core facility: MOBICYTE. This core is dedicated to applications in the field of ecotoxicology, but also ecology functional and integrative ecophysiology. Among all our aim, we work on better understandings of technical confusing factors. More and more manufacturer proposed flow cytometry device particularly this 5 last years. All allow to analyze cell parameters but with different technologies. A lot of team works on same biomarkers, but some variation on protocol and method to analyze data are done. Based on this observation, we would like to harmonize the analyzed process from sample preparation to analyses raw data. First step was based on a consortium of six partners, all equipped with different manufacture flow cytometer, to assess the variability attributable to the equipment. In this study, a human monocyte cell line, THP-1, was chosen in order to have a homogeneous cell population to limit the variability of the measured responses. THP1 are exposed to set of increasing concentration of toxic agent, cadmium and cell mortality are revealed using a fixable fluorescent probe. Once labelled and fixed, cells pre-exposed to cadmium or not, are aliquoted and shipped to consortium for, analysis. Each laboratory analyzed sample set and determine both EC50 of cadmium and an unknown concentration. Raw data have been send to MOBICYTE for global analysis. For each set of sample analyzed on each cytometer, two data analysis was performed. The results obtained with the global analysis reveal a greater variability due to human component. Two immune functions are under study with same design: phagocytosis activity and oxidative burst.

TH161

Assessing the influence of part per billion variation of natural organic carbon levels on cationic polymer acute toxicity to D. magna

E.R. Salinas, BASF SE / Experimental Ecotoxicology; J. Bozich, University of WisconsinMilwaukee / SFS; L. Peters, BASL SE; R. Lukas, BASF SE

Cationic polymers (CPs) are chemicals used widely for a variety of industrial and commercial purposes, for example, as floccing agents in water clarification. CPs generally have a low environmental concern due to the presence of organic carbon in surface water that greatly reduces their bioavailability, even at low mg/L levels. Although dissolved organic carbon can be as high as 50 mg/L in European surface waters, regulatory aquatic testing guidelines (OECD and EPA) limit total organic carbon (TOC) in clean dilution water to < 2 mg/L to determine the baseline toxicity of chemical substances. However the amount, source and quality of the organic carbon in dilution water can vary considerably between testing laboratories. To better understand the influence of minute TOC differences as a potential sources of variation for clean water studies, we explored the impact of 0.25, 0.50 and 1 mg/L additions of TOC (as humic acid) in artificial water (Elendt M4 medium) on CP toxicity, all of which are considered by definition to be clean dilution water. We chose *Daphnia magna* to assess the acute toxicity of CPs with varying molecular weights and cationic charge density. Our results indicate that part per billion levels of TOC produced strong CP toxicity mitigation. These results suggest that background TOC in dilution water is a potential source of variation and should be considered when interpreting the results of aquatic toxicity studies. Therefore, we recommend that aquatic tests used to establish the baseline toxicity of cationic polymers should be standardized with added TOC in the dilution water at a minimally measurable amount (1 mg/L) to quench low level variability of background TOC and represent an environmentally realistic worst case exposure.

TH162

Development of standardised methods in environmental toxicity assessment of nanomaterials

J. Farkas, SINTEF Materials and Chemistry; A. Booth, SINTEF Materials and Chemistry / Environmental Technology; D. Altin, BioTrix; L. Støen, SINTEF Materials and Chemistry

In order to allow a reproducibly assessment of potential effects of pollutants a standardisation of ecotoxicity tests is necessary. While a range of standardised tests on environmental impacts of pollutants is available, their implementation in nano-toxicity testing is difficult and many of those methods are unsuitable for assessment of engineered nanomaterials (ENM). Small changes in environmental parameters or testing procedures can change the physico-chemical characteristics of the tested ENM and thereby influence the study results. In order establish guidelines and standard procedures for ecotoxicological assessment of ENMs, the NanoReg project aims to test, optimise and validate a set of suitable test methods for different types of ENMs. Preparation and characterisation procedures, a prerequisite for ENM toxicity evaluation, were established and validated for different ENMs in laboratories across Europe. Further, standard tests for toxicological assessments using the freshwater aquatic species *Pseudokirchneriella subcapitata* and *Daphnia magna* were evaluated and adapted to suit needs for ENM testing. A wide range of ENMs from various material classes are tested for their environmental stability and their potential ecotoxicological effects using the adapted ENM-standardised methods. The tested materials include different carbon based ENMs (native and modified single- and multi-walled carbon nanotubes, graphene and graphene oxide); a range of modified and unmodified titanium dioxide (TiO_2) based ENM, as well as metal ENMs. This large scale testing with suitable standardised methods will provide valuable ecotoxicological data and further show if a read across or grouping approach of similar ENMs is possible. Similarities between ENMs such as size, material and surface for potential read across or grouping approaches in aquatic toxicity tests can be identified.

TH163

Spill risks from Hazardous and Noxious Substances (HNS) - Is standard toxicity data enough?

M. vannoni, J. Aldridge, D. Doran, S. Davis, Cefas; M. Kirby, Cefas / Ecotoxicology; T. McGowan, FERA; D. Sheahan, Cefas

Over the last decades shipping of chemicals at sea have increased significantly leading to the need to be prepared to respond to incidents involving hazardous and noxious substances (HNS). Typically during chemical spills the impact upon marine organisms is estimated using spill model predictions of time-weighted average (TWA) or peak concentration compared to a predicted no effect concentration derived for constant exposure toxicity studies conducted in the laboratory. This study evaluates the toxicity of two chemicals, aniline and benzalkonium chloride, comparing standard and brief exposures. Salinity and temperature were also taken into consideration to understand the behavior of these chemicals under potentially different seasonal and regional conditions. Toxicity was evaluated for the copepod *Tisbe battagliai*, the red algae *Ceramium tenuicorne* and the brown algae *Fucus vesiculosus*. Benzalkonium chloride and aniline showed EC_{50s} in a similar concentration range (1-2 mg l^{-1}) based on standard exposures. When brief exposures were considered, contrasting effects for the two test chemicals were shown on all the species tested. Exposure to benzalkonium chloride resulted in significant effects after 1 hour exposure to a concentration of 5 mg l^{-1} but for aniline recovery of Tisbe (the most sensitive species to this chemical) occurred in exposures of a few hours at concentrations up to 300 mg l^{-1}. For variations in salinity and temperature toxicity decreased for some chemicals with the increase in salinity while increased temperature generally increased toxicity. Thus, a spill of a chemical with a specific mode of toxicity results in greater effects following relatively brief exposures, and exposed organisms show little or no recovery. In such cases impacts might be expected to be more extensive and persistent. In conclusion, for chemicals with specific modes of toxic action brief exposures, and possibly limited spill profile studies may be useful to support chemical spill risk assessment. Parallel studies on factors such as temperature and salinity are also valuable to help predict the likely scale of impact from chemical spills in different locations i.e. in the mouth of estuaries or further offshore or during different times of year or in different parts of the world.

TH164

RHIZOtest - the first standardized laboratory bioassay designed to assess the environmental bioavailability of trace elements to plants in soils

M. Bravin, CIRAD; L. Lemal, RHIZLAB; C. Chevassus-Rosset, M. Montes, CIRAD; D. Arnal, P. Hinsinger, INRA; E. Doelsch, CIRAD

A lot of laboratory bioassays were developed to assess the toxicity of trace elements on plants and among which some are widely used and even standardized at an international level. Surprisingly, there was no laboratory bioassay developed to assess the environmental bioavailability of trace elements to plants, that is to say the uptake of trace elements in plants. Considering the ecotoxicological relevance of the environmental bioavailability endpoint, we developed and tested a dedicated laboratory bioassay, the RHIZOtest, to allow its recognition and standardization it at an international level. The RHIZOtest is a plant-based test initially developed in the 1990s and used as a research tool to investigate the role of root-induced chemical processes as a driver of trace element dynamic in the rhizosphere and bioavailability to plants. The RHIZOtest is notably characterized the small size of the system and by a physical separation between plant roots and soil that enables to collect easily and quickly both compartments separately. These characteristics led to evaluate its performance as a risk assessment tool. We first assessed the robustness, the repeatability and the reproductibility of the RHIZOtest via an international ring-test. The RHIZOtest was hence validated for the measurement of the environmental bioavailability of arsenic, cadmium, cobalt, chromium, copper, lead, nickel, and zinc to three target plant species (tomato, cabbage, and fescue). We secondly assessed the ability of the RHIZOtest to distinguish the environmental bioavailability of trace elements for different plant species. Using a scoring approach, we were able to classify 10 plant species as a function of the bioavailability endpoint. Finally, we assessed the ability of the RHIZOtest to distinguish the environmental bioavailability of trace elements for plants grown in different soils. We thus exposed tomato, cabbage, and fescue to 55 soil samples exhibiting very constrasted physical-chemical properties. Armed with this knowledge, a draft describing the RHIZOtest tool and methodology was submitted to the international organization for standardization (ISO) and was validated as new standard, the NF EN ISO 16198, in February 2015. The development of the RHIZOtest is going on with its application to other contaminants such as nanoparticles and trace organic contaminants.

TH165

The leaf fatty acid composition of plants: new biomarker as a standard for assessing soil quality.

M. LE GUEDARD, LEB AQUITAINE TRANSFERT-ADERA / LEB AQUITAINE TRANSFERT; J. BESSOULE, CNRS - Université de Bordeaux / Laboratoire de Biogenese Membranaire UMR

The leaf fatty acid composition is proving to be a powerful biomarker to diagnose soil pollution. This biomarker is based on the fact that when plants are exposed to pollutants on soils, the reactive oxygen species (ROS) can increased dramatically and lead to cellular damages, including lipid peroxidation. The main target of lipid peroxidation is lipids containing polyunsaturated fatty acids, and more particularly linolenic acid (C18:3) mainly associated with lipid plastid membranes. We previously carried out numerous studies on the leaf fatty acid composition of lettuce grown under control conditions (*ex situ* approach) on contaminated and control soils and we showed that the %C18:3/(%C18:0 + %C18:1 + %C18:2) fatty acid ratio, called "Omega-3 index", decreased in leaves under stress. From these *ex situ* studies, it appeared that the Omega-3 index of lettuce leaves is an earlier bio-indicator than the standard tests existing in plant, such as emergence or growth inhibition. Moreover, we demonstrated that the Omega-3 index is a rapid, sensitive (metal and organic contaminants), robust, reproducible and repeatable biomarker of soil pollution which is then able to generate reliable data. These *ex situ* development of the Omega-3 Index led in 2012 to the publication by the French Agency for Standardization (AFNOR) of a soil quality standard (XP 31-233). We further studied this biomarker with plants grown on real sites during the French ADEME program "Bioindicators of Soil Quality". The results acquired during this program (among others) highlighted the efficiency of the leaf fatty acid composition of various plant species harvested on several areas of contaminated sites to provide an excellent biomarker of organic and metal contamination of soils. From these *in situ* studies, it was also developed and published a "mathematical" method with which it is possible in complex situations to analyze results provided by the use of the Omega-3 Index *in situ* and to rank different areas of the same site according to their phytotoxicity. Following these results, a standardization of the Omega-3 Index as a tool to assess soil quality through the International Organization for Standardization (ISO) goes underway with a desired applicability both ex and *in situ*.

TH166

Use of Standardised Methods and Risk-Based Approach in the Oil Industry

K. Wadhia, Opus / Environmental

A testing programme was implemented to investigate the management of produced waters using a risk-based approach. In employing this approach using standarised protocols, Whole Effluent Assessment (WEA) would potentially constitute an appropriate means of detection of unknown substances and has the advantage that each unique discharge is tested, rather than relying on predictive field toxicity values. Whole Effluent Assessment (WEA) was carried out on 15 platforms in the UK Continental Shelf as part of an assessment of the applicability of WEA as part of a risk based approach for the monitoring of produced water in the offshore industry. Installations were chosen to give a broad coverage of location, type of production (oil, gas), stage of production (early, late) and characteristic of produced water (oil content, water cut, use of chemicals and complexity of produced water) based on previous biannual data submitted. The UK study was carried out in parallel with other studies in Norway, The Netherlands and Denmark. WEA testing was carried out using bioassays from three trophic levels; bacteria (MARA and LumiMARA), algae (*Skeletonema costatum*) and crustacean (*Acartia tonsa*). WEA testing was carried out on produced water samples collected offshore at the same sampling point/time as samples were collected for biannual chemical sampling. Toxicity of the whole effluent during the RBA trial was found to be more representative of the risk compared with that of the individual substances. Thus was more indicative of the actual risk posed. Also the major contributing substances to the overall risk could be identified and the contribution of the natural components was determined to be significant. The study provided a comprehensive evaluation of the hazard and exposure assessment for characterisation of risk using bioassays and analytical techniques including modelling to formulate the UK RBA implementation programme. **RBA, WEA, Standardised, Risk**

PLATINAAE, an analytical platform for your research in environmental chemistry

P. Masson, INRA Institut National de la Recherche Agronomique / USRAVE Platform Platinaae; A. Richard, INRA Institut National de la Recherche Agronomique / US LAS Platform Platinaae; C. Mougin, INRA (Institut National de la Recherche Agronomiqu / UMR ECOSYS

Ecotoxicological studies need high quality measurements of chemical contamination within all the compartments (physicochemical and biological) of the environment. In consequence, analytical laboratories must produce traceable analytical data, with high level of confidence, in numerous complex matrices. PLATINAAE (PLATeforme d'INgéniérie Analytique pour l'Agriculture et l'Environnement) is the central platform for analytical chemistry of INRA (French National Institute for Agricultural Research) mainly dedicated to plant and soil analysis. This platform is supported by two laboratories located at Arras (LAS) and Bordeaux (USRAVE). Both are equipped with high-performance instrumentation and are accredited according to the standard ISO 17025. In USRAVE, PLATINAAE works mainly on plants. It is capable of preparing and analyzing all parts of a plant (fruits, stems, roots, leaves, needles, wood...), and all types of plants (trees, cereals, grasses, fruits and vegetables...). The analyses concern the major elements essential to plant growth (nitrogen, phosphorus, potassium...), and trace elements, especially metallic trace elements with direct effects on the environment or health (arsenic, cadmium, lead, mercury...). In the LAS, PLATINAAE performs measurements on soils. The analysis done in this unit concern pedo-agronomic analysis (pH, particle size distribution, P, K, Ca, Mg, organic matter…), environmental analysis for metals (Cd, Pb, Hg, As…) and also for organic polluants (pesticides, herbicides, dioxins, PCB, PAH…). The determinations may be done as total content or as bioavailable content.

PLATINAAE works essentially as a partner for research programs. The main themes investigated are environmental contamination, biogeochemical cycle of elements in various ecosystems (crops, lands, forests...), soil quality, food chain or plant physiology. PLATINAAE performs also analyses on living organisms (invertebrates…) and wastes (sludge, compost…). In these scopes, the platform participates to numerous programs for environmental observation and experimentation, such as the ICOS Ecosystem program, the European program Biosoil, the RMQS network, RENECOFOR (monitoring of French forests)… PLATINAEE develops also innovative methods in analytical chemistry according to the needs of its partners (samples of very small sizes, trace and ultra-trace elements such as lanthanides or PGEs, mapping of plant organs…).

Biochem-Env, a platform of environmental biochemistry for research in ecology and ecotoxicology

N. Cheviron, V. Grondin, INRA Institut National de la Recherche Agronomique / UMR ECOSYS Platform BiochemEnv; S. Nélieu, O. Crouzet, M. Hedde, INRA Institut National de la Recherche Agronomique / UMR ECOSYS; C. Mougin, INRA (Institut National de la Recherche Agronomiqu / UMR ECOSYS

The consortium AnaEE-France (http://www.anaee-s.fr) aims at understanding and predicting the biodiversity and ecosystems dynamics in a context of global change. It will allow improving the understanding of biotic processes/environment interactions, mobilizing experimental and modelling platforms devoted to the biology of continental ecosystems, both terrestrial and aquatic. In this context, the objectives of the platform Biochem-Env (http://www.biochemenv.fr) are to provide skills and innovative tools for biochemical characterizations of soils, sediments, and micro-macro-organisms living in terrestrial and aquatic ecosystems. These approaches aim to assess ecosystems functioning. The scope of the platform Biochem-Env includes: -the technology intelligence and the development of tools used for the biochemical characterization of solid environmental matrices and macrofauna, -the development of an Environmental Information System (referential for functional biodiversity) for managing the traceability of samples and data, and improve our ability to characterize the biological status of environmental matrices. Available as a scientific partner in the frame of collaborative research projects, the platform's abilities ranges from advice providing (sampling, protocols and data analysis), to technical training, including analysis and experimentation in regional, national and international research programs. The tools of the platform have been deployed in programs targeted at assessing the sensitivity and restrictions of biological indicators of soil quality, subjected to various constraints (waste landfilling, farming practices, contaminated sites and soils…). For example, long-term experimental sites provide opportunities to assess the effects of pressures and threats on soils and their functioning. In a context of soil contamination, we can conclude using global soil enzymatic activities that soil functioning is enhanced in biological farming comparatively to conventional practices.

TH169

MOBICYTE: mobile cytometry in environmental risk assessment

D. RIOULT, UMRI 02 INERIS-URCA-ULH SEBIO / MOBICYTE flow cytometry core facility; A. Bado-Nilles, INERIS; J. Porcher, INERIS / INERIS UMRI SEBIO ECOT; S. Betoulle, URCA / UMRI SEBIO

Commonly used in biomedical science, flow cytometry is more and more implemented in environmental sciences allowing studies on numerous cell types such as bacteria, yeasts, phyto / zooplankton and invertebrates and vertebrates cells. Environmental cytometry requires adaptations of techniques in cellular biology. Developments of field methodologies are required in order to study cell organizations and functions closed to their interactions with environmental variables and environmental stress in wild contexts and with taking into account of samples quality preservation. In this context, the mobile environmental flow cytometry core facility named MOBICYTE is dedicated to applications in numerous scientific fields and particularly in environmental toxicology and ecotoxicology, but also in functional ecology and integrative ecophysiology. This core can be used by research teams as well as by public and private organizations working in environmental biomonitoring programs. Our mobile equipment is operable in the more isolated environmental field contexts (aquatic and terrestrian), considering cell models from various animal species (algae, mollusk, fish, wild mammals…). Some studies using MOBICYTE platform will be described in order to present new opportunities for biomonitoring the health status of wildlife organisms in health and environmental risk assessments contexts.

Analysis of 13-year soil monitoring data of Korean Soil Quality Monitoring Network

S. Jeong, Kunsan National University / Dept of Environmental Engineering; J. Kim, S. Lee, Kunsan National University; Y. An, Konkuk University / Department of Environmental Heath Science

The Korean soil quality monitoring network has been operated since 1987 and has yearly reported concentrations of soil trace elements for 1,521 observation points. This study analyzed 13 year soil monitoring results (1997-2009) of Korean soil quality monitoring network. The monitoring results were reported with concentrations and land uses for 9 trace element concentrations (Cd, Cu, As, Hg, Pb, Cr^{6+}, Zn, Ni, and F). This study analyzed tolerance limits of the trace element concentration data for each observation point. This study classified 278 points as "variation occurred", showing that the upper 95% tolerance limit of the variation occurred point data was greater than the Korean soil quality standard. This study also evaluated anthropogenic contamination of those points by deriving background concentrations from the total soil quality monitoring data. Analysis results showed that fluoride levels were frequently varied in Korean soils and industrially-used sites showed significant changes in trace element concentrations. However, this study found that high nickel concentrations of soil monitoring data were attributed to naturally high background concentrations. This study also suggested better soil quality monitoring network strategies for achieving sustainable soil environment. The most important strategy for producing reliable soil monitoring data is to sample soils at the consistent points every monitoring time. (This study was supported by the GAIA project (2014000560001) funded by Korea Environmental Industry & Technology Institute and Korean Ministry of Environment.)

TH171

"Métatox": a new one-year training program for engineering students on assessment and management of toxicological risks for both human and ecosystem health

J. Faburé, INRA/AgroParisTech; L. Fechner, Irstea/AgroParisTech; F. Mariotti, V. Camel, INRA/AgroParisTech

In recent years, the global contamination of our environment has generated a major challenge: understanding the long-term impacts of multi-exposures to a multitude of chemical substances at low doses. Current regulations evolve with the increase of concerns regarding the impact of anthropic activities on both human and ecosystem health. Today, these concerns are essential for citizens, politicians, managers and firms. As a consequence, all industries have now to integrate their impact on the environment and the human health, since the assessment of the innocuousness of a substance or product, towards both humans and ecosystems is now a part of the evaluation of manufacturing processes and development of new products. In this context, AgroParisTech, the leading French Graduate School in Agronomy, Environment, Life science and Food technology, has created a new one-year training program for engineering students that develop a holistic approach of toxicological risks for humans (environmental and food toxicology) and ecosystems (ecotoxicology) health. "Métatox" is one of the specialized programs offered to the students as a last year of their Master of Engineering; it is co-organized with Anses (French Agency for Food, Environmental and Occupational Health & Safety) and Ineris (French National competence centre for Industrial Safety and Environmental Protection). "Métatox" students get in-deep knowledge and skills on the impacts of contaminants on living organisms (including humans) and ecosystems, with an integrated, multidisciplinary approach. "Métatox" offers the necessary background in chemistry, biology, ecology, statistics and modelling to understand the fate of chemicals in the environment and the mechanisms of their toxic effects at different levels of biological organization. In addition to this fundamental knowledge, practical teachings initiate the students to the methods and tools covering the full range of risk analysis: risk assessment, management and communication, especially in the framework of the European regulations (i.e. REACh, EU Water Framework Directive, Biocides Directive). With this interdisciplinary course and systemic approach, the future engineers will both fully analyse a wide type of risks, and propose efficient actions and management strategies to protect human and environmental health.

TH172

Petnica Science Center: A place for engaging science education in Southeastern Europe

T.D. Mišljenović, Petnica Science Center / Institute of Botany and Botanical garden Jevremovac; B. Mićić, N. Božić, Petnica Science Center

Petnica Science Center (PSC) is an independent, non-profit organization for science education in Serbia. PSC has over 35 years of experience in organization of programs for gifted high school and university students, as well as educational and outreach programs for science teachers. Among the 17 programs at PSC available to students, over 40% are related to biology, chemistry and environmental sciences. Nearly 2500 alumni from over 450 academic institutions and companies, together with PSC`s team of trained professionals, form our network of associates, lecturers and peer educators, all of whom are involved in course design and who help put on our numerous activities and programs. Each year, 1500 students from Serbia and Southeastern Europe attend programs at PSC. Since a major reconstruction completed in 2012, PSC currently represents the most modern center for extracurricular science education focused on young people in Europe. PSC houses fully equipped state-of-the-art laboratory facilities for biology, chemistry, and physics. PSC also houses a scientific library with 40.000 books and journal acces. PSC also provides full board accommodation options for up to 170 participants at a time. A multidisciplinary approach is the hallmark of all PSC activities, which requires efficient integration of all our laboratories, instruments, students, and associates. Specific facilities include a laboratory for cell cultures and molecular biology, a center for confocal microscopy, HPLC-MS and GC-MS equipment, a laboratory for analyses of trace elements equipped with an AAS and XRF, plant growth chambers, as well as several 3D printers and a 3D scanner, all of which are situated in one central laboratory building. The characteristics of PSC as a unique venue led to major changes in the concept of the most recent Young Environmental Scientists (YES) Meeting, organized by the Students of SETAC. The 4th YES meeting was hosted by PSC in March 2015, and for the first time in a YES meeting we offered hands-on short courses for 130 meeting participants. All 8 courses took place in one day simultaneously for all students. PSC's laboratories equipped with cutting-edge instruments and our network of dedicated alumni and associates and partners make PSC one of the most convenient and engaging venues to host hands-on courses, summer schools, and scientific conferences related to current topics in environmental science.

How can we improve the link between academic research and policy-making in order to advance chemical risk assessment and management? (P)

TH173

Regular information of stakeholders and policymakers about a soil monitoring of persistent organic pollutants in Cuba

A. Escobar Medina; I. Hilber, Agroscope ART; D. Sosa Pacheco, R. Faure Garcia, L. Aguiar Díaz, CENSA; N. Bartolomé, Agroscope ISS / Analytical Chemistry Natural Resources Environmental Protection in Agriculture; T. Bucheli, Agroscope ART / Environmental Analytics Natural Resources and Agriculture

Although Cuba has signed, ratified and put into force the Stockholm Convention on Persistent Organic Pollutants (POPs, 2008), there exists no systematic monitoring tool that would reflect and assess the environmental and human exposure for chemicals. Cuba has been active in the Strategic Approach to International Chemicals Management (SAICM). In a project from 2010 to 2011 funded by SAICM, the United Nations Environment Programme (UNEP) and the Global Environment Facility (GEF) POPs were monitored globally (including Cuba) and passive air samplers were installed to evaluate the exposure. With our project, Soil-Q (Establishing a soil monitoring network to assess the environmental exposure to polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs) in the province of Mayabeque, Cuba), the investigation on POPs in Cuba has been reactivated by monitoring the soil. The newly established soil monitoring network in Cuba currently consists of 39 sample locations in the province of Mayabeque, and additional 12 stations in the adjacent province of Havana. From these sites, representative soil samples were taken, using the rigorous protocol of the Swiss Soil Monitoring Network (NABO). Analytical methods for the quantification of PAHs and PCBs have been established in the laboratories of the Cuban partner. Results indicated low rural exposure with these pollutants (max. 110 μg/kg of the sum of the 16 PAHs regulated by the EPA, max. 5 μg/kg of the sum of the 7 non-dioxine like PCBs). In contrast, concentrations at some places in Havana are considerable and mandate remediation. Workshops were held (initial and to present the above results) to decision makers (representatives of the agricultural, energy, environmental, and chemical safety sector). Present were also members from the Swiss Embassy and the Swiss development and Cooperation in Cuba (COSUDE). The echo and interest in the audience was high because Soil-Q covers the urgent demand of Cuban policymakers and stakeholders to know the POP pollution in their soils. The Cuban TV was also used for the dissemination of first results and an explanatory website about Soil-Q and its long-term aim is planned at the Cuban partner institute of agriculture (CENSA). Soil-Q is as a promising start to advance in the chemical risk assessment and management and has, as stakeholders and decision makers were approached from the beginning, a high potential for future research and related dialogues.

TH174

An Analytical Framework to Evaluate and Ameliorate Science-based Policy-Making in relation to complex environmental concerns using the latent constructs, Legitimacy and Effectiveness

J.g. Gardner Le Gars, University of Exeter / Biosciences; C. Tyler, Biosciences College of Life and Environmental Sciences; R. Owen,

The effectiveness and legitimacy of science based policy-making in Europe for the endocrine disruptor 17α, ethinyl-estradiol (EE2) is challenging to evaluate. Traditional policy performance measurement tools predominantly target regulatory compliance downstream of the policy development process. A dearth of tools to evaluate upstream policy processes such as scientific risk assessment and legislative proposal development hampers analysis of the legitimacy and effectiveness of policy-development processes. The use of science to guide policy decisions is hence rarely, systematically evaluated or monitored. Consequently, understanding of causes and potential solutions to effectiveness and legitimacy deficits is severely curtailed risking sub-optimal policy outcomes and loss of trust in both governing authorities and the scientific expertise upon which they rely. The present study characterizes specific challenges of environmental risk policy interventions with respect to EE2 thereby facilitating recognition of the following issues confronting policy-makers: i) scientific & economic uncertainty in relation to adverse effects, their consequences and potential mitigation and management options, ii) low-consensus deliberative processes typified by values and interests divergence, iii) high complexity derived from social pluralism, institutional diversity and inter-regulatory dependencies. An analytical framework is derived pursuant to an extensive literature review and operationalized via a qualitative study in order to facilitate a systematic evaluation of variables impacting effectiveness and legitimacy in the case of EE2 policy interventions. The legitimacy of deliberative processes, the implementation thereof and concomitant participant discourse is evaluated and the effectiveness of resulting policy outcomes discussed. More specifically, the discourse of participants to deliberative processes at key decision points in the policy development process is analysed. Variables influencing the development of policy-makers' perception of risk (constructivist risk), the role of science therein and predominant cognitive mechanisms employed to transpose scientific evidence into decision outcomes are thereby identified. Understanding of the challenges of applying & using science and its relative influence on outcomes of policy-making processes is thereby greatly enhanced.

TH175

Socio-Economic Impacts of Copper Compounds Classification in Industrial Sites

L. Perez Simbor, European Copper Institute; S. Van Passel, Department of Engineering Management, Faculty of Applied Economics, University of Antwerp

Regulation 1907/2006/EC concerning the Registration, Evaluation, Authorization and Restriction of Chemicals (REACH), offers risk management measures to assure safe use of dangerous substances. Regulators use socio-economic and environmental considerations to assess impacts of applying those measures. However, it remains a challenge to properly assess the effects of risk management measures in several industrial sectors. Currently, the integration of the cost and benefits of applying harmonized classification on substances is not included in the decision-making process. The implementation of harmonized classification has direct and indirect consequences for industrial sectors and ecosystems such as the provisions to transport the substances. This research uses an integrated economic-environmental analyses to assess the trade-off of applying harmonize classification in industrial sectors. It includes provisions for organizational and investment cost and, as a novelty, incorporates the external environmental cost and benefits, based on ecosystem services quantifications. The integrated method is applied in several case studies based on recent regulatory decisions that impact the European Copper industry. The results show that the environmental benefits of applying the measure cannot overcome the side-effects and the costs for industrial sites in a twenty years period.

TH176

MACRO-DB: A Risk assessment tool for management of pesticide use in water protection areas in Sweden

M. Gönczi, SLU / Centre for Chemical Pesticides; N. Jarvis, SLU / Soil and environment; J. Kreuger, Swedish University of Agricultural Science / Centre for Chemical Pesticides

In Sweden, farmers are not allowed to use plant protection products on agricultural fields located in water protection areas for abstraction of drinking water, without permission from the municipality. The risk of a pesticide leaching to groundwater or surface water is dependent on several factors and their combined effects cannot be easily predicted. There are 290 municipalities in Sweden and the assessments are performed in many different ways sometimes resulting in a high degree of inconsistency in the outcome of the decisions. This causes differences in the level of protection of the drinking water in Sweden as well as unequal conditions for the farmers, which causes conflicts between farmers and the local authorities in many municipalities. The Centre for Chemical Pesticides (CKB) at the Swedish University of Agricultural Sciences has developed a risk assessment tool, MACRO-DB, to help the municipalities to assess the risk of pesticide contamination of the drinking water. MACRO-DB is based on the MACRO model which is a one-dimensional, process oriented, dual-permeability model for water flow and pesticide transport in agricultural soils. MACRO-DB is a simplified, user-friendly tool in two steps, mainly aimed for environmental inspectors, farmers and agricultural advisers. The first step is a very simple web application based on worst case scenarios. In the second step there are a limited number of parameters that the user needs to identify to run the model; site specific information on soil properties, crop, active ingredient, dose and time for application. Predefined sets of parameters for each regional climate, soil class, crop type and pesticide are provided in the tool, as well as pedotransfer functions for soil hydraulic properties. The results are given as a simulated concentration in the water, at 2 m soil depth, which will reach the groundwater and a simulated concentration in the water leaving the drainage system, which will reach the surface water. MACRO-DB was released in September 2013 and the tool is now used in many municipalities in Sweden. MACRO-DB makes it possible for the local authorities to base their decisions on best scientific knowledge. The results can also act as an independent, common foundation for discussions between the different stakeholders, which can help preventing unnecessary conflicts.

Advances in Social Life Cycle Assessment and Life

Cycle-based Sustainability Assessment (P)

TH177

Communicating results in a life cycle sustainability analysis

T. Ekvall, H. Ljungkvist, IVL Swedish Environmental Research Institute

We developed an approach to life cycle sustainability analysis (LCSA) where the research questions are case-specific and defined in a participatory process. The LCSA results are likely to be a mix of quantitative modelling output and qualitative discussions on widely divergent topics. Communicating such complex results is a challenge. We applied the LCSA approach to the case of a 50 km pipeline for transfer of residual heat from industries to a large district-heating system. The LCSA included 14 research questions on economic, environmental and social aspects. We communicated the results not only in a report, but also in a powerpoint presentation with one slide for the response to each question. The content of the slides ranged from bar charts to bullet points. To make the presentation more uniform, we used a happy, neutral or sad smiley on each slide. The conclusions were summarised in a table with the smiley and a very brief comment for each question. We found this presentation efficient for communicating our interpretation of the results. However, it did not allow for communicating the methodological choices, assumptions etc. that are necessary for the audience to assess our results and conclusions. Instead, we saw a tendency for the audience to accept the smileys without further reflection. In conclusion, smileys are highly efficient for communicating conclusions on widely divergent issues, but they do not create a good basis for discussion of the results and analyses. This means they might close the door for debate over the decision at hand. This is a problem since our participative LCSA approach is particularly relevant for cases that greatly concern several different stakeholders, and debates are important to resolve conflicts of interest. Hence, communicating not only the conclusions of an LCSA study but also the complexity of the study remains an important challenge.

TH178

Sectorial analysis of the current state of life cycle sustainability assessment in the Chemical Industry: insights from the MEASURE project

D. Kralisch, Friedrich-Schiller-University Jena / Institute of Pharmacy; A. Manent, Evonik Technology & Infrastructure / Process Technology Engineering; E. Rother, Evonik Technology & Infrastructure GmbH / Process Technology Engineering; D. Schowanek, Procter & Gamble / Brussels Innovation Center

The Horizon 2020 SPIRE Program has developed a clear vision for the future of the European process industry for a more sustainable, competitive and growing economy. Ambitious reduction targets have been formulated for energy and raw material intensity and for greenhouse gases emissions. Cross-sectorial collaboration along the value-chain is key to achieve these objectives. Harmonization of methods for life cycle sustainability assessment (LCSA) along the value-chain is necessary to allow a consistent quantification of the overall benefit of the alternative strategies developed within the SPIRE program. In this context, the European project MEASURE (Metrics for Sustainability Assessment in European Process Industries) was launched aiming to address critical issues and gaps in sustainability assessment. A sectorial analysis was conducted for several process industry sectors. In this poster, special attention is given to the sector Chemistry and Consumer Goods and challenges for the implementation of LCSA. Overall, a good degree of consistency is observed in this sector concerning life cycle indicators used. The WBCSD Guidance Document "Life Cycle Metrics for chemicals" (2014) is seen as a useful fundament. Nevertheless, some topics were identified as critical issues leading to remaining inconsistencies. Industries face many challenges for assessing (eco)toxicity due to unresolved methodology issues, low data availability, results' sensitivity and practical interpretation. Currently, toxicity issues assessed via LCA are rarely included in the decision-making process and play a minor role despite the recognized relevance of the indicator itself. The assessment of bio-based products remains also a critical issue: biogenic carbon is often inconsistently considered over the life cycle, the calculation of the emissions from Land Use Change are lacking harmonization, while other aspects such as the impact on biodiversity or land quality are poorly covered. Recommendations to tackle some of these issues will be presented to improve the implementation of LCSA. Finally, industries of this sector have gained experience in assessing sustainability along the innovation process thanks to R&D adapted tools, and a staged assessment process starting with the use of screening tools based on selected indicators and ending up with a full Life Cycle Analysis. Such approach will be presented and recommended to assess projects and their innovations in the SPIRE context.

TH179

Development of Life Cycle Social Impact Assessment Method Using Covariance Structure Analysis

Y. Ichisugi, N. Itsubo, Tokyo City University

In recently years, Social Life Cycle Assessment has been paid attention. In 2013, UNEP/SETAC Life Cycle Initiative published a report about S-LCA, which describes a list of subcategories and candidates of indicator. However, there is very little information regarding cause–effect chain models indicating the relationship between inventory and impacts in society. The development of a method for S-LCA with clarification of cause-effect chain is critically important to improve the quality of assessment. ISO37120-Sustainable development of communities-was standardized in 2014. This provides a list of indicators for sustainable development in city service. There are a hundred of indicators with classified into seventeen themes. WCCD (World Council on City Data) published statistic data that meet with the indicators listed in ISO37120. Therefore, this study attempts to develop a framework of S-LCA method using statistic data which characterize social aspects of cities in the world. We use covariance structure analysis. This study draws Social Impact Pathway based on covariance structure analysis result.

TH180

Safe and Sustainable Chemicals, from question to method

S. Waaijers, University of Amsterdam/IBED Institute; M. Zijp, National Institute for Public Health and the Environment RIVM / DMG; M. Broeren, University of Utrecht / Copernicus Institute; L. Posthuma, RIVM / Centre for Sustainability Environment and Health; L. Shen, McGill University / Chemical Eng; E. Heugens, National Institute for Public Health and the Environment RIVM / Centre for Safety of Substances and Products

Developments such as depletion of resources and climate change urge a transition to a sustainable economy. But what is sustainability? A popular way to evaluate sustainability in terms of impacts on man and the environment is life cycle analysis (LCA). A drawback of LCA is the extensive amount of data needed and environmental, health and safety (EHS) aspects are generally not fully taken into account and are not compatible with substance regulations. Just as important is the necessity for defining the sustainability question to be answered. In many cases the choice for a method is based on habit or nice of expertise and not made explicitly. The aim of this study was to obtain insight in sustainability assessment methods currently used for or applicable to chemical products, biobased compounds, and production processes of substances, to structure these and organise it into a sustainability assessment identification key. We developed this identification key for manufacturers, policy makers and those who perform sustainability assessments. The applicability of this approach is shown in a case study. Four cases were chosen, two feedstocks and two products: organic waste, sugar beet, chemical building blocks and bioplastics. Stakeholders were selected, interviewed and brought together within workshops to discuss their views on sustainability, the use of LCA methods, and knowledge gaps. An overview of the stakeholders' questions regarding sustainability will be given and the application of the identification key is illustrated. In this way a transparent translation of theory and aims (definition of sustainability and promoting sustainable development) is put into practice, which is an often-missing link in current sustainability case studies in literature. *Acknowledgement* - This research is carried out in the framework of RIVM Strategic Programme (SPR), in which expertise and innovative projects prepare RIVM to respond to future issues in health and sustainability. We gratefully acknowledge the Athena Institute of the VU University Amsterdam for sharing their expertise and assisting in the stakeholder analysis and participation.

TH181

Screening of sustainability indicators for conventional renewable energy systems

D. Garrain, CIEMAT / Energy Energy Systems Analysis Unit; D. Iribarren, Instituto IMDEA Energía / Systems Analysis Unit; M. Fuss, F. Cao, W. Poganietz, KIT Karlsruhe Institute of Technology / Institute for Technology Assessment and Systems Analysis ITAS; J. Dufour, Instituto IMDEA Energía / Systems Analysis Unit; Y. Lechon, CIEMAT / Energy Dpt Energy Systems Analysis Unit

Sustainability indicators are increasingly important to decision- and policy-makers. Within the framework of the EERA Joint Programme on Economic, Environmental and Social Impacts of Energy Policies and Technologies ("EERA JP e3s", www.eera-set.eu), a specific sub-programme working on "A life-cycle approach for evaluating the sustainability performance of energy technologies" was launched in 2013. The goal of this sub-programme is to develop and harmonise indicators and methodologies used to evaluate environmental, social and economic impacts of energy systems. Within this context, a review of more than 100 articles and reports on the evaluation of energy systems was carried out. The strategy followed for the identification of appropriate sustainability indicators focuses on analyses at the sub-sector level. This work complements previous studies on bioenergy systems by screening sustainability indicators for conventional renewable energy systems: hydro, geothermal, solar and wind power systems. After removing recurrent indicators, 150 indicators reported in the literature were evaluated and screened according to the following criteria: life-cycle perspective, practicality (availability and reliability), and relevance (specificity to the sub-sector assessed). A reduced set of indicators was therefore defined, not only covering the three sustainability dimensions (environmental, economic, and social) but also including multi-dimensional indicators (e.g., techno-environmental and socio-economic indicators). The selection of environmental-related indicators was found to be significantly affected by the specific sub-sector under assessment, in contrast to social and economic indicators.

TH182
Identifying sustainability indicators through Open Space
T. Ekvall, IVL Swedish Environmental Research Institute
Sustainability is a broad concept with a large number of environmental, economic and social aspects. Any sustainability assessment can cover a selection of these aspects only. The choice of aspects and indicators is vital, since it can heavily affect the conclusions of the assessment. Different aspects will be crucial in different case studies. A case-specific approach that involves stakeholders in the selection of assessment indicators is likely to increase the perceived relevance of the results and the chances that the results of the assessment are accounted for in the decision process. The Open Space technology is well suited for discussing and deciding how to organise an activity where the structure is not known in advance. It has been used for, e.g., organising a conference, addressing a local societal challenge, and developing an action plan for a non-governmental organisation (NGO). The Open Space format for workshops is designed to create ample opportunities for meetings and discussions, where each individual participant has the freedom to join and leave discussions whenever he/she chooses. Individual deliberations and small-group discussions alternate with reporting and discussions in plenum in order to generate and preserve the energy in the meetings. Deciding on the topics and the schedule of the workshop is part of the workshop itself. We organised Open Space workshops at the initial stage of a life-cycle sustainability analysis (LCSA), inviting concerned companies, NGOs, policy makers, and researchers. We found the output from the workshop useful as basis for prioritising among the sustainability aspects and for formulating research questions for the LCSA, although this required an interpretation of the workshop results. We also found it necessary to add further research questions to make the LCSA sufficiently comprehensive and balanced. A key challenge in LCSAs with Open Space workshops is to obtain a sufficiently large and representative group of participants in the workshop. This is likely to be possible primarily in cases that greatly concern several different stakeholders, such as policy decisions or investments in infrastructure.

Challenges in data analysis, weighting, valuation and visualisation - How to enable decision makers to make trade-offs while being transparent for all stakeholders (P)

TH183
Exploring feasibility of monetarization and water footprint
A. Gallice, Veolia / Research Innovation; H. Imbeault-Tétreault, CIRAIG Polytechnique Montreal; A. Boulay, CIRAIG - École Polytechnique de Montréal / Chemical engineering department; J. Serre, VERI; S. Mehier, Veolia / Research Innovation
In a context where stakeholders ask for understandable results to support reliable decision making and communication, the subject of monetary valuation is prevailing. Moreover, companies began to notice increases in their exposure to risks (environmental and business risks) due to several reasons: access to resource, increase in price, supply disruptions, lower quality of resource, competition for resource allocation between stakeholders including local population, etc. Life Cycle Assessment and Footprint metrics do not appear to be very intuitive to decision makers used to monetary values. Monetarization is seen as a valuable way of expressing LCA and footprint results but still needs to be investigated further. This work, jointly carried out by Veolia R&I and CIRAIG, aims to investigate possible applications of monetarization to water footprinting. Work is based on the Water Impact Index methodology from Veolia (Bayart et al., 2014). First, a critical review of the literature on the issue of monetarization of potential impacts and risks associated with water has been conducted aiming to put into perspective the different approaches. The term impact includes in particular resource depletion and loss of ecosystem services, while the term risk here means business risk associated with environmental impacts. Second, a critical analysis of the limits and scientific relevance in a context of multi-criteria decision has been performed. Finally, preliminary recommendations on how monetarization can be applied to water footprint are suggested. Keywords: Water Footprint, Water Impact Index, Monetarization, Weighting. References: Bayart, Jean-Baptiste; Worbe, Sébastien; Grimaud, Julien; Aoustin ; Emmanuelle. 2014. The Water Impact Index: a simplified single-indicator approach for water footprinting. *The International Journal of LCA*. Vol 19; p. 1336:1344.

TH184
The Ecological Scarcity Method: Deriving Country-specific Environmental Targets for Definition of Critical Flows
L. Schebek, TU Darmstadt / Material Flow Management and Resource Economy; G. Selvakumar, TU Darmstadt; N. Jansky, Technische Universitat Darmstadt / Institute IWAR Material Flow Management and Resource Economy; S. Wellge, Volkswagen Group Research Enviroment
The Ecological Scarcity Method (ESM), also called Ecopoint Method, is based on a distance-to-target approach: it defines critical flows which denote a target level for selected physical flows to the environment, and compares these flows to the current respective flows, leading to so-called eco-factors. Critical flows and current flows are to be specified for defined system boundaries, usually the national level, which for the original ESM is Switzerland. The ESM has been applied in the framework of company environmental management of the Volkswagen AG (VW) since 2001. At VW's German sites the ESM has been adapted to German framework conditions in the course of a research project. As a next step the ESM shall be transferred to VW's international sites. However, this poses specific challenges for which a methodological approach has been worked out. The relevant eco-factors were first allocated to the related environmental problem and grouped according to the level in terms of global, regional or local impacts. For each of these groups, which were allocated based on the scientific basis of the concept of Planetary Boundaries, a preferred conceptual framework for identification of environmental targets has been proposed resulting in the Top-down-, Spatial- and the Bottom-up-approach. As a second step a comprehensive research of data bases, statistics and literature in order to assess data availability for critical as well as current flows for the proposed approaches modified the grouping from environmental problems to the level of impacts. Data related to global environmental problems belonging to the Top-down-approach were collected from international organisations. For the spatial- and bottom-up-approach data was drawn from international data bases or accessed from national organizations. From this research, a viable procedure for identification of environmental targets for each eco-factor was identified. For the issue of energy consumption procedures for down-scaling national targets from an international perspective have been worked out and compared to national policy goals. Results show the outcome of policy strategies on environmental targets and related critical flows.

TH185
Comparative life cycle assessment of alternative solutions for the management of medical equipment discarded: the case of a panoramic X-ray dental machine
G. Tomasoni, Università degli Studi di Brescia / Department of Mechanical and Industrial Engineering; M. Collotta, I. Barberá Franch, M. Alberti, University of Brescia / Department of Mechanical and Industrial Engineering
In 2012 in the European Union there were 11,000 hospitals and 68,000 medical institutions (including long-term care facilities, clinics, specialized clinics, laboratories, etc.), with about 3,000,000 beds for acute illnesses. The supply of healthcare services is highly dependent on the use of medical equipment, whose employ is continuously increasing. Moreover, the use phase of the life cycle of medical equipment is very short. In fact, the adoption of new standards, the need to improve safety and functionality of the equipment and also marketing purposes contribute to a continuous renew of the medical equipment: It is estimated that in European hospitals a medical equipment is averagely used only for 5 years. This brings to an increasing amount of medical equipment disposed. Once disposed, most of the medical equipment become a WEEE, i.e. a Waste of Electrical and Electronic Equipment, which represents both a serious risks for the environment, primarily due to their content of hazardous materials, and at the same time, if properly managed, a valuable resource. Considering healthcare institutions, scientific literature highlight that not enough attention is payed to medical WEEE, which are often neglected, stored in basements or in unused premises or donated to charity organization for their shipment in poor Countries without any warranty on their real destiny. Therefore, it is very important to promote a proper management of medical WEEE within healthcare institution. In this work, a comparative life cycle assessment is performed to assess the environmental implications of different realistic solutions for the end of life of a panoramic X-ray dental machine. This work is part of the Life-MED project (LIFE13 ENV/IT/000620), funded by the European Union through the Life financial instrument.

TH186
Public decision support & LCA: feedback from testing a simplified LCA tool for wastewater systems
L. Guérin-Schneider, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR GEAU; L. Catel, IRSTEA Montpellier / UMR ITAP ELSA; E. Couliou, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR ITAP ELSA; M. Tsanga, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR GESTE; P. Roux, National Research Institute of Science and Technology for Environment and Agriculture Irstea / UMR ITAP ELSA
The environmental efficiency of a wastewater treatment plant (WWTP) is usually assessed through its effluents quality. But this quality is achieved at the expense of other impacts occuring during the construction, operation and dismantling of the whole wastewater system (WWS) including sewers and WWTP. Many studies performing LCA of WWTPs already exist, but there is a lack of simplified and operational tools usable by non-specialists of LCA to perform LCA of entire WWSs. The objective of this work was to develop a simplified software providing objective environmental indicators to be included in the decision making process along with other criteria when chosing among WWSs options. To reach this goal, specifications for a simplified software were defined and a first version was implemented (namely ACV4E software). The potential users are public

wastewater services and engineering consultancies. The LCA results should be presented to local authorities for decision making and in some cases to citizens to justify the choices made. ACV4E was applied to real cases, to test the software as well as the appropriation process and the effects on decision making. In addition a working group involving stakeholders was created. This group made a focus on the interpretation of LCA results, with the challenge of making them understandable and usable for non-specialists of LCA. The experiment suggests that the co-construction of the calculator with potential users is crucial for appropriation. It partially opens the LCA black-box and allows to better meet field needs. However, classical mid/endpoint bar charts proved to be inefficient for non-specialist interpretation and for communication to politicians and normalisation of the results almost always leads to misinterpretations. As a result of the working group process, these classical charts will be replaced by new types of representations. Local authorities that tested ACV4E were very interested in this tool even if the environmental criterion was often secondary compared to other criteria in a decision context (like compliance with legal standards and financial aspects). Finally, this experiment concludes that such a tool was more difficult to use directly by local authorities for which the need for LCA in decision making for WWSs choices is not frequent enough. Engineering consultancies could be the main users of the software because they have technical skills and will have more regular use of it.

TH187

Interpretation of LCA results for GRP pipe systems through normalization lenses

V. Vladimirov, HOBAS; M. Pazdro, REICHHOLD AS

HOBAS and REICHHOLD took a significant step in direct collaboration of both product R&D and life cycle assessment. The study evaluates the different choices of unsaturated polyester resins (UPR) for cc-GRP pipe systems, from a LCA perspective. To this purpose three types of resin have been used to manufacture HOBAS products and the environmental impacts were compared. The resins are: (a) Standard UPR, (b) UPR resin containing recycled PET material (denoted rPET-UPR) and (c) UPR resin containing bio-sourced material (denoted BIO-UPR). Based on EN 15804:2012 (Sustainability of construction works) the study compares fourteen impact indicators for pipe systems in the three scenarios. After the results were obtained and interpreted, normalization was applied in order to cross-check the first understanding of the indicators. CML data from April 2013 (Leiden University, CML-IA, Version 4.2, April 2013) was taken and the total emissions for Europe "EU25+3" (Wegener Sleeswijk et al., 2008) were used as the reference scenario. For example, for a product manufactured with BIO-UPR resin in the first step increased variation of "renewable energy", "water consumption", "stratospheric ozone depletion" and "photochemical ozone creation" were noticed from the calculation. The results of the second step, normalization, indicate that the impact category with by far the most relevance is the "depletion of abiotic resources". Therefore, the issues which could be considered for further analysis may concern the use of crude oil (i.e. the formulation of the BIO-UPR resin includes intermediates made from crude oil). Thus, choice of BIO-UPR resin is a rather complex process and can hardly be reduced to the simple question of, for instance, which resin generates more or less CO2-eq emissions for the product. The use of normalization is of great help in identifying possible next steps in product R&D. The BIO-UPR formulation used in this study is one possibility of many. Based on the LCA results, focus can be put on elements that matter most. For the polymer industry the development of alternative and renewable raw materials represents a key task. This study represents a step ahead on the path to sustainability!\n\n

TH188

Allocating an environmental load to wastewater sludge when sludge moves from "waste" to "product", a methodological challenge

M. Pradel, Irstea Clermont Ferrand / Ecotechnologies; L. Aissani, Irstea Rennes; J. Villot, Ecole des mines de Saint Etienne; J. Baudez, Irstea / TSCf research unit; V. Laforest, Ecole des mines de Saint-Etienne - Institut Fayol / UMR CNRS EVS

Wastewater sludge is currently considered as a waste but with new industrial practices and european regulation (End-of-Waste directive) considerate will be soon a valuable product. This paradigm shift must be followed by the consideration of environmental constraints to introduce this new product on market. Assessing the environmental performances of these future 'marketable sludges' can be processed with Life Cycle Assessment (LCA) but it first implies to take into consideration the whole life cycle of this new product from the raw material extraction up to the product end of life. How this can be reasonably done when waste LCA consider that the waste is free of any environmental load when entering the system, assumption often known as the "zero burden approach"? Giving a environmental load to "product sludge" consists in the resolution of several methodological questions which arise as the wastewater treatment plant will provide several coproducts : the clean water and the sludge, both having a merchandable value. This paradigm shift implies that the wastewater treatment plant has several function and multifunctionnality has to be resolved. Because sludge is a direct and indivisible production from water treatment, process subdivision cannot be achieved. In the same basis, system expansion can be barely used as there is no known alternative to the "wastewater treatment" if system is expanded to only keep the "sludge production" one. Finally, allocating an environmental burden to these two coproducts appears to be the best way to solve the induced multifunctionnality. As a consequence, allocation factors have to be developed to allocate an environmental burden both to the sludge produced and to the clean water released in the receiving media. This is quite challenging as it supposed (i) to model the sludge production both from primary treatement and biological treatment, (ii) to create new allocation factor based on these physical and biological processes as classical allocation factors cannot be used, (iii) to validate these allocation factors whatever the wastewater treatment plant configuration. This paper aims at presenting the allocation factors used to charge sludge with an environmental burden when sludge is from now considered as "product sludge".

TH189

Integrating LCA and risk assessment for decision support

Y. Dong, S. Miraglia, M.H. Faber, Technical University of Denmark; M. Hauschild, DTU Management Engineering / DTU Management Engineering

In the last decades, the use of classic decision making theory has gained a lot of attention as decision support tool. Indeed, when stakeholders and governments face the problem of decision making over public safety and health or sustainable development, their judgment has to be justified to the community by objective proofs. In this perspective, sustainability and safety are the major issues to be considered in decision making. Decision makers always face the dilemma that the most sustainable solution may not be the safest one. Therefore, it is a challenge to optimize the system, ensuring sustainability and at the same time minimize risks. The Global Decision Support Initiative (GDSI) is a cross-disciplinary center established at the Technical University of Denmark (DTU) aiming to develop a new framework model for decision support with associated tools to solve this problem. Firstly a Life Cycle Assessment (LCA) is conducted to screen the studied system and identify the hotspots where emissions are largest and hazards are more likely to occur. Decision analysis is then applied to optimize the alternative that may reduce the consequences caused by those hotspots. To start with, we first identify and characterize the potential hazards and then quantify their associated direct and indirect consequences for each hotspot. A finite number of available actions are chosen among the ones that can reduce the consequences. For each action we apply decision analysis to evaluate the effect of the actions in mitigating the consequences, expressed in failure cost and damages to human health. Meanwhile, we apply LCA to assess the environmental impacts changes caused by the action. A common metric is developed to allow comparing RA and LCA results on a common scale and eventually integrate them into one result. The result is then used to rank the alternatives, taking stakeholder preference into consideration, and the optimal solution is identified. Here the traditional LCA is applied in the framework of decision making together with RA. It does not only identify the problem, but also provides ranking of possible solutions, where consequences from both potential risks and environmental emissions are considered. This framework is flexible and can be broadly used to support decision at different scales, e.g. national, sector or product level.

A normalisation and weighting procedure (ESA) to assists the decision making process: The case study of salt mining in the chlor-alkali industry

M. Margallo; R. Onandia, University of Cantabria; J. Laso; A. Bala; P. Fullana; R. Aldaco, A. Irabien, University of Cantabria

Life cycle assessment (LCA) is a powerful tool to assess the potential environmental impacts throughout a product´s life-cycle [1]. However, LCA results comprises several impact categories that makes difficult the process comparison [2]. To reduce the LCA complexity, this work proposes a normalisation and weighting procedure to carry out the environmental sustainability assessment (ESA) of the extraction and purification of salt in the chlor-alkali process. The ESA is based on two main variables: natural resources sustainability (NRS) and environmental burdens sustainability (EBS) [3]. Different variables play an important role in the quantitative estimation of the NRS, mainly the materials, water, and energy usage need to be considered. Three main EBS are involved depending on the natural environment: air, water, and soil and related to the emissions, effluents, and wastes leading to different environmental impacts. Nevertheless, these functions are rarely normalised thus remained as functions rather than variables. This methodology suggests the normalisation of EBS based on the threshold values proposed in the European Pollutant Release and Transfer Register E-PRTR, and a similar procedure based on the average consumption of natural resources of the process under study for the normalisation of NRS. Moreover, the normalised indicators can be subjected to a weighting procedure to obtain a global index that will help the decision making process. However, the use of an absolute index could potentially mask certain results. For this reason, the comparison of several processes by means of a global index can be used to obtain an overview of the environmental performance of the system and to optimise the process. Nonetheless, individual indicators should be also assessed to determine the main environmental problems and thus provide opportunities for improvement of the critical points of the process.

TH191
Representativeness of environmental impacts in relation to Life Cycle Inventories
A. Esnouf, E. Latrille, J. STEYER, Institut National de la Recherche Agronomique, Narbonne-France / UR Laboratoire de Biotechnologie de lEnvironnement; A. Helias,
Life Cycle Assessment is based on Life Cycle Inventory (LCI) of systems that identifies all emissions to the environment and consumptions of resources (1,800 referenced environmental flows in the Ecoinvent database). LCIs show many sources of variability due to the diversity of systems, the model uncertainties, the variations of the real world... Following the construction of LCIs, emissions and consumptions are translated in terms of environmental impacts through a set of impact categories. Different Life Cycle Impact Assessment (LCIA) methods (ReCiPe, TRACI, CML, Eco-indicator...) propose different ways of characterizing categories and each of them can be used to determine the results on the set of impact categories modeled. Then, LCIA methods reduce the complexity of systems comparison from a 1800-dimension space (i.e. the number of substances emitted or taken from the environment) into a less than 20-dimensional problem (i.e. the impact categories) where each dimension has an environmental meaning. Each impact category represents, to a more or less precise extent, the original LCI. The aim of the present work is to determine how far impact categories are relevant. The method automatically organizes impact categories according to the information on LCIs that they gather. LCA results interpretation could be helped by this development by indicating the impact categories for which the LCI is the most correctly represented. The 11,332 LCIs of the Ecoinvent 3.1 database and a total of 692 impact categories were used in the present work. Both of them belong to a vector space of 1,769 dimensions where each dimension represents an environmental flow. After a data pre-processing (i.e., data cleaning and data normalization), cosine squared between directions of LCIs and impact categories were computed. The higher a cosine is, the more the impact category direction is simillar to the LCI direction, and the more correctly the impact category considered represents the contribution of each environmental flow. Cosine squared results for each impact category were compared by using their median value. Grouping categories by their environmental meaning shows tendencies from eutrophication potential to land occupation/transformation for their ability to accuratly represent LCIs from Ecoinvent.

TH192
Promoting Innovation & Technology in Europe: Sustainability Support and Information Network of Infrastructure
W. De Soete, Ghent University / EnVOC
In the roadmap to a resource efficient Europe, it is indicated that a sustainable and guaranteed supply of raw materials will be essential, together with an efficient transformation and use of the resources. The EIT (European Institute of Innovation and Technology) Raw Materials will contribute to this challenge, but to boost effective and efficient resource management in the EU, insight and support is required in sustainability of virgin resource extraction, recycling, resource conversion and environmentally, socially and economically sustainable technologies in general. The SSIC (Sustainability Support and Information Centre) and facilitates sustainable technological development and educational activities by making use of a state-of-the-art sustainability assessment toolbox. This Network of Infrastructure (NOI) project brings partners together with complementary expertise and therefore is the central contact point for industry and technology developers, from resource extraction to product design and recycling, when it comes to questions regarding input-output analysis, life cycle assessment, life cycle sustainability assessment, socio-economic assessment, sustainability of material flows and stocks, cost benefit analysis, recyclability benefit calculations, criticality analysis, supply disruption etc. It can be consulted in up-scaling projects, other NOIs, education, training etc. but will also be leveraged outside the EIT Raw Materials and will link up with existing initiatives at European level. Offering a fast and effective access to state-of-the-art datasets, methodologies and tools, the SSIC delivers a service package at the highest level for innovation growth in Europe. While looking for opportunities to strengthen the consortium by networking and linking to other initiatives, fostering collaborative projects with SSIC and external partners, the consortium will add through a multidisciplinary approach in making raw materials a major strength for Europe.

Contaminants of Emerging Concern in the Environment and their Management (PC)

MOPC01
Pesticide contributions of urban effluents and storm sewer on a French peri-urban river contamination
V. Dufour, EPOC - UMR 5805 CNRS / UMR EPOC LPTC; D. Granger, M. Capdeville, LyRE - SUEZ; J. Cruz, K. Le Menach, P. Pardon, University of Bordeaux / UMR EPOC LPTC; N. Pouly, Bordeaux Metropole; B. Barillon, CIRSEE - SUEZ; M. Chambolle, LyRE - SUEZ; H. Budzinski, University of Bordeaux / UMR EPOC LPTC
Currently, pesticides are widely used by different users such as farmers, private consumers or public authorities. These compounds can be released into the environment and contaminate water resources, potentially impacting aquatic ecosystems. Several contamination routes are well identified: diffuse losses due to agriculture uses, or direct releases because of urban effluents. Storm sewers and wastewater treatment plants (WWTP) are known to be vectors of pesticides. Indeed, several studies have shown the presence of pesticides in wastewaters; moreover WWTPs are not able to remove all of them efficiently without adequate tertiary treatments. The purpose of this work was to study a continuum including a wastewater network, up to the collection natural aquatic ecosystem, a peri-urban river, receiving treated WWTP effluents and untreated inputs via storm sewers. This has allowed us to identify the main contributors of pesticides to the river contamination. It has been shown that the major source of pesticides used in agriculture is the upstream of the studied system, as expected, mainly due to metabolites of metolachlor (0.2 $g.d^{-1}$), one of the most used herbicide on the territory. On the contrary, WWTP effluent appeared to be the major vector for pesticides mainly used for urban purpose such as fipronil (0.5 $g.d^{-1}$) a veterinary used insecticide or diuron (2. $g.d^{-1}$), an herbicide added in paintings for building protection against mosses and algae. Domestic wastewaters are suspected to bring more pesticides than industrial ones because some pesticides are classified as biocides and are mostly used by private consumers such as fipronil. Storm sewers have been shown to be also a source of contamination, but at a lower level than WWTP effluents. Such integrated studies by documenting the presence, sources and fate of pesticides all along a continuum could give paths for reflection and *in fine* actions on sources, to reduce pesticide contamination of natural surface waters. *Acknowledgement* This study benefited from funds in relation with RESEAU and "Plan Micropolluants" projects (associating as partners: Bordeaux Métropole, SUEZ, IRSTEA, Water Agency, CNRS, University of Bordeaux, CHU and Aquitaine Regional Council). This work was funded by the Aquitaine Regional Council and SUEZ. This study has been carried out with financial support from the French National Research Agency (ANR) in the frame on the Investments for the future programme, within the Cluster of Excellence COTE (ANR-10-LABX-45)

MOPC02
Pollutant fluxes in small catchments: Impact of urbanization, flow dynamics, and pollutant degradation
G. Guillet, Tübingen University / Applied Geoscience; H. Rügner, Eberhard Karls Universität Tübingen / Hydrogeochemistry Center of Applied Geosciences; M. Schwientek, Eberhard Karls Universität Tübingen / Hydrogeochemistry Center for Applied Geosciences; B. Kuch, Institute for Sanitary Engineering Water Quality and Solid Waste Management University of Stuttgart; P. Grathwohl, Eberhard Karls Universität Tübingen / Hydrogeochemistry Center for Applied Geosciences
Urban areas are responsible for the release of numerous emerging contaminants into the environment. Wastewater-related compounds are constantly introduced into aquatic systems by wastewater treatment plants (WWTPs). Hydrophobic chemicals such as PAHs are mainly released during flood events and the related combined sewer overflows. Within catchments, rivers act as transport pathways. While some pollutants undergo attenuation, others are very persistent. In this study emerging and particle related pollutant fluxes are assessed for the Steinlach and the Ammer rivers, two tributaries of the River Neckar in SW-Germany. For dissolved pollutants (e.g. pharmaceuticals and personal care products as carbamazepine, diclophenac or triclosane), fluxes have been estimated based on various sampling campaigns including monthly samplings and high-resolution sampling during base flow and flood conditions. By use of Lagrangian type sampling at consecutive control sections, also the persistence of these pollutants could be assessed. In water samples collected during event samplings, a correlation of total concentrations of hydrophobic pollutants (PAHs) with turbidity and/or total suspended solids was found, which allows for the calculation of pollutant concentrations on suspended solids. For both catchments, such correlation coupled with continuous monitoring of discharge and turbidity enabled the calculation of particle-bound pollutant fluxes. The results showed that fluxes of wastewater-related pollutants are preferably influenced by consumption patterns and WWTP efficiency. During flood events, these compounds tend to get diluted, revealing a source limitation of their input into the environment. Among these compounds diclofenac shows the highest fluxes in the monitored rivers. However, it must be reminded that dissolved compounds can undergo natural attenuation processes. In that regard, their fluxes decrease with distance from the source. Carbamazepine – as a counterexample – also shows high fluxes but behaves conservatively and may spread along farther distances. Results of on-line turbidity monitoring showed that high turbidity/discharge events account for the majority of particle-related pollutant loads. In contrast to soluble compounds, the mass fluxes are positively correlated with discharge, yet practically cease during base flow conditions. On the long run, however, both types of pollutant fluxes may be relevant and should be monitored to a sufficient level.

MOPC03
Modified-zeolites as potential sorbents for removal of per- and poly-fluoroalkyl substances from aqueous environments
L. Li, University of British Columbia / Civil Engineering; M. Hedayati, The University of British Columbia / Dept of Civil Engineering; M. Kim, The Universtiy of British Columbia / Department of Civil Engineering; M. Jeronimo, The University of British Columbia / School of Population and Public Health Occupational and Environmental Health
Perfluoroalkyl substances (PFASs) are a class of stable chemicals used in fire-fighting foams, industrial surfactants, insecticides and surface treatments for paper and textiles. Perfluorooctane sulfonate (PFOS), its salts and perfluorooctane sulfonyl fluoride (PFOSF) were added to Annex B of the Stockholm convention on persistent organic pollutants (POPs) in May 2009. A number of sites, such as landfills, agricultural sites and sites treated with biosolids (sewage sludge) have been contaminated by PFASs. PFASs have also been found in groundwater. Limited work has been done on PFAS removal from aqueous environments. Sorbents (e.g., activated carbon, zeolite, peat etc.) for conventional organic pollutants might not be effective for remediation of PFAS. Knowledge of sorption processes and appropriate material types (i.e., sorbents) for PFASs is limited. Also most recent studies have only focussed on PFOS and PFOSF. In our study, we modified a natural zeolite (clinoptilolite) to provide four sorbent materials and investigated their sorption potential for nine PFASs. The results based on the 24-h batch adsorption test were promising. CPC-zeolite and DDDMA-zeolite are the most effective among the four modified-zeolites in removing PFASs from aqueous environment. The sorption ranks were PFOS > PFNA > PFHxS > PFOA > PFHpA > PFBS > PFHXa > PFPA > PFBA. The modified sorbents had higher concentration removal for long-chain than for short-chain PFASs. For the same number PFAS carbon atoms, sorbents had higher sorption of PFSAs than PFCAs. This research is on-going. We continue to investigate sorption kinetics, temperature effects, maximum sorption capacity, sorbent dosage effects, particle-size effect, PFASs competition effect, as well as the stability of these sorbents and the leachability of sorbed PFASs. Keywords: Perfluoroalkyl, sorption, modified-zeolite, aqueous. *Acknowledgement* – Thanks to the Natural Sciences and Engineering Research Council of Canada Grant # EGP477520-14.

MOPC04
Human exposure to plasticizer chemicals - correlation between indirect and biomonitoring exposure estimates in a Norwegian human cohort.
G. Giovanoulis, IVL Swedish Environmental Research Institute Ltd / IVL Swedish Environmental Institute; A. Alves, Flemish Institute for Technological Research VITO NV; T.T. Bui, IVL Swedish Environmental Research Institute Ltd / Natural Resources Environmental Effects; A. Palm Cousins, IVL Swedish Environmental Research Institute Ltd; J.A. Magnér, IVL Swedish Environmetal Research Institute Ltd / IVL Swedish Environmental Institute; A. Covaci, University of Antwerp, Toxicological Center / Toxicological Center Dept of Pharmaceutical Sciences; S. Voorspoels, Flemish Institute for Technological Research VITO NV; C.A. de Wit, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES
Plasticizers used as additives in numerous consumer products have a continuous release into the environment (pseudo-persistent), leading to consecutive human exposure which might cause adverse health effects (e.g. endocrine disruption). Indoor air quality and house dust may have significant impact on human health because people spend most of their time indoors, where the concentrations of plasticizers are comparatively high. Inhalation and dermal exposure through air, transdermal exposure through dust adhered to the skin, oral exposure through dust ingestion (hand to mouth contact) and diet have been considered as major exposure pathways. On the other hand, daily intake of plasticizers can also be determined through analysis of urinary metabolites. In the present study, indoor stationary air, personal ambient air and house dust (floor and elevated surfaces) samples were collected, extracted using solid phase extraction (SPE) and/or microwave assisted extraction and analyzed by GC-MS/MS. Based on the resulting concentrations of the diesters in these external media, we calculated the daily human intake rates for the Norwegian cohort, and compare them with reference tolerable daily intakes (TDI) for each analyte. Alternatively, the human biomonitoring approach allowed us to assess to which extent plasticizers entered the bodies of 61 adults living and working in the Oslo area (Norway). Finger nails and three intraday urine spots were collected from each participant in order to

monitor their internal concentration. The analysis of nine phthalate metabolites, together with two DINCH metabolites in urine and nails was performed by LC-MS/MS and used to back-calculate the initial total exposure to the parent compounds. Among phase I metabolites, high levels of the monoesters of DEP and DnBP were observed in nails (median concentrations of MEP 31.2 ng/g and MnBP 21.4 ng/g), while in urine the median concentrations of the more specific biomarkers of secondary metabolic oxidation for DEHP were OH-MEHP 4.5 μg/L and 5-oxo-MEHP 4.7 μg/L, and for DINCH were cis-OH-MINCH 0.5 μg/L and cis-cx-MINCH 0.5 μg/L. The correlation of indirect exposure estimates and human biomonitoring exposure estimations is under investigation.

MOPC05

Method development for non-target screening of sewage sludge using comprehensive two-dimensional gas chromatography coupled to high-resolution mass spectrometry (GCxGC-HRMS)

C. Veenaas, Umea University / Chemistry; P. Haglund, Umea University / Department of Chemistry

More than 100,000 chemicals are present in the technosphere and 30,000 of these are considered to be so-called "every-day chemicals". Sewage treatment plants (STPs) are used to remove nutrients, but also some metals and organic chemicals, from urban waters and create a less contaminated effluent. Consequently, STPs form a link between the technosphere and the environment. A by-product of the sewage treatment process is sewage sludge – a solid product that contains nutrients as well as pollutants. These nutrients make the sewage sludge attractive for applications as fertilizer on agricultural fields, provided that the contaminant levels are not too high. In order to be able to investigate pollutants occurring in sewage sludge an analytical method for comprehensive non-target screening is needed. Up till now there is no method existing that allows a full screening of sewage sludge for a wide variety of compounds with different properties, which is the ultimate goal of this project. The current work has aimed at developing a validated non-discriminating sample preparation method for gas chromatography - mass spectrometry (GC-MS) analysis. Pressurized liquid extraction (PLE) was used for extraction, with in-line and/or off-line clean-up. In the in-line approach silica gel was added to the PLE cell for simultaneous extraction and clean-up, whilst the off-line approach involved clean-up by gel permeation chromatography. Analysis was performed by comprehensive two-dimensional GC (GCxGC) coupled to high-resolution MS in both cases. Good recoveries were obtained for all tested compounds with either one or both of the proposed sample preparation methods. Therefore the combination of both methods allows a comprehensive screening of sewage sludge contaminants by GC-MS.

MOPC06

Illicit drugs as new class of emerging contaminants in aquatic systems: high specific level of contamination in French West Indies compared to global monitoring results

D.A. Devault, Université Paris Sud / Ecologie Systématique et Evolution; T. Néfau, Observatoire Français des Drogues et des Toxicomanies (OFDT); L. Karolak, UMR 8079; Y. Levi, Univ. Paris Sud

Since 2013, authors analysed each year illicit drugs (19 molecules and metabolites related to cocaine, cannabis, amphetamines, opiates and substitute consumption) in urban wastewater inlets of treatment plants (WWTPs) of Fort-de-France, the main city of Martinique island of French West Indies. Caribbean are the hub of cocaine trafficking and a hotspot of cannabis production. This area is also a hotspot for biodiversity, including several patrimonial species and ecosystems, on which the effect of emerging pollutant residues is unknown. Wastewater were daily sampled during a normal week, i.e. without festive event or other confusing factor, following a protocol framed by the European Union's programme SCORE, gathering now worldwide similar initiatives. Samples were analysed (solid-phase extraction on Oasis HLB cartridges then LC/MS-MS quantification) after SCORE inter-calibration agreement. Results show very high concentrations of cocaine and metabolites in comparison to published results,, exceeding 3 μg/L for benzoylecgonine (BZE) and 1.5μg/L for 11-nor-9-carboxy-delta-9-tetrahydrocannabinol (THC-COOH): this levels are ten-fold higher than those published for other cities. Opiates and their substitutes and amphetamine-like compounds were never detected. This data confirm a Caribbean-specific profile of drug consumption, partly explained by the place of this archipelago in the international market of drugs. Considering to temperate environment, some results begin to demonstrate ecotoxicological effects for European or North-American species at environmental concentrations, i.e. tenfold less than results from Martinique. Moreover, severe leakage of sewer and non-collective sanitation threaten surface water. Combining the small watercourse of the river and the local high population density, coastal and marine ecosystems could be rightly be considered as exposed to such molecules, in combination with pharmaceutical residues. Authors will discuss the potential input of illicit drugs on the aquatic environment in Martinique Island, the predicted values regarding to actual data on ecotoxicological effect of the studied molecules, and the mean to ward off the urgent need for determining the stake of such emerging micropollutants on the accelerating biodiversity loss observed in patrimonial ecosystems.

MOPC07

Toxicity of the biocide and plastic additive Triclosan to marine organisms: environmental risk assessment

R. Beiras, University of Vigo; T. Tato, Universidade de Vigo / ECIMAT; S. González, University of Vigo; l. vidal, ECIMAT; P. Sanchez Marin, University of Vigo / Ecology and Animal Biology

The 5-cloro-2- (dichlorophenoxy) phenol, or Triclosan, is a biocide of general spectrum widely used in multiple pharmaceutical and personal care products (including tooth paste) and also as an additive to different kinds of plastics. We have tested the toxicity of this substance by means of three standard marine bioassays representing sensitive and phylogenetically distant biological models, including the microalgae *Isochrysis galbana* , nauplii larvae of the copepod crustacean Acartia and embryos of the echinoderm *Paracentrotus lividus*. In increasing order of toxicity, the EC_{50} (μg/L) for sea-urchin embryos was 149 (95% CI: 140 to 158) the LOEC 120 μg/L and the NOEC 100 μg/L. For *Acartia* nauplii the EC_{50} was 94,3 (95% CI: 88,73 to 99,79) and the EC_{10} was 64,8 (95% CI: 53,69 to 75,81). For the microalga the toxicity was even higher, with a EC_{50} of 34 (95% CI: 28 to 40), a LOEC 20 μg/L, and a NOEC of 10 μg/L. These results allowed us to quantify the risk posed by Triclosan on coastal ecosystems. The results also suggest that Triclosan concentrations should be surveyed in coastal waters, and water quality standards implemented for this substance.

Microplastics in the environment: Sources, Fate and Effects (PC)

MOPC08

Occurrence, composition and adverse effects of microplastics in native mussels collected along coastal and marine areas of the northern Adriatic sea

A. Gomiero, International Research Institute of Stavanger / Enviromnent; P. Strafella, National Reseach Council of Italy / Institute of Marine Science; T. Maes, Cefas / EQT; G. Bruno, National Research Council of Italy / Institute of Marine Sciences; A.G. Viarengo, Universita del Piemonte Orientale / Department of Sciences and Technological Innovation DiSIT; G. Fabi, National Research Council of Italy / Institute of Marine Sciences

In the recent years, the occurrence of microplastic particles in the aquatic environment has gathered a rising scientific interest. Several studies proved that the ingestion of microplastics may negatively influence the physiology of marine organisms of different feeding strategies, particularly in those species which can not discriminate the food source. Recent studies have posed the attention to the accumulation of these particles in the food web and the direct consequences to the human heath as even larger amounts of seafood are consumed nowadays. On the other hand, evidences also suggest the role of microplastics as vectors of chemical pollutants either used as additives during the polymer synthesis, or adsorbed directly from seawater i.e., PAHs, PCB, surfactants etc,. However, models simulating physiological conditions in the gut suggest that both adsorbed pollutants and chemical additives of plastics might be released to organisms. Despite the importance of microplastics in adsorption and transport of hydrophobic pollutants, little is known about the distribution, accumulation in the marine food webs as well as their direct and indirect harmful effects. On this context, the Adriatic Sea represents a semi-enclosed basin characterized by a low water recirculation rate and an elevate anthropic pressure associated with unsustainable fishing and high inputs of environmental contaminants. Thus the primary objective of this study was to investigate the body burden accumulation, polymers characterization and eco toxicological effects in native blue mussel (*M. galloprovincialis*) collected in various marine areas along the northern Adriatic sea. Results were compared to data collected from native populations of coastal areas. The early outcomes both show a significant site-, time- and oceanographic conditions-related distribution and support the needing of a seafood safety monitoring program to better understand the actual human health related risk.

MOPC09

Microplastic particles analysis by Raman micro-spectroscopy and chemometrics: morphological and chemical characterization

L. Frère, LEMAR UMR 6539 CNRS; J. Moreau, Ifremer, Laboratoire Détection, Capteurs et Mesures - Centre Bretagne; I. Paul-Pont, C. Lambert, P. Soudant, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; A. Huvet, Ifremer, LEMAR UMR 6539 CNRS/UBO/IRD/Ifremer; E. Rinnert, Ifremer, Laboratoire Détection, Capteurs et Mesures - Centre de Bretagne

World production of plastics has been steadily increasing since 1950, reaching 311 million tons in 2014. This results in an accumulation of plastics in the marine environments. The global spread of microplastics requires the establishment of standard analytical methods to distinctly identify them and estimate their abundance in all environmental matrices (water, sediment and biota). Most studies have used visual sorting to rank a particle as a microplastic but this method presents a high probability of a misidentification, especially with decreasing particle size. To date only a few studies on the detection and chemical composition analysis of microplastic particles have been published. Several methods have been developed to identify plastic polymers such as vibrational spectroscopy like micro-Fourier-transform infrared (FT-IR) spectroscopy and

Raman spectroscopy, which are non-destructive methods, and sequential pyrolysis-gas chromatography coupled to mass spectrometry (destructive method). The main disadvantage of these methods was the analysis of only selected subsamples and not the whole sample. In the present study, an alternative method was proposed to rapidly analyze all particles in a sample with Raman micro-spectroscopy. Three laser wavelengths (633, 691 and 785 nm) and three substrates (glass fiber filter, nitrocellulose membrane filter and gold coated microscope slide) were tested to increase the ratio between Raman intensity and fluorescence background. The analysis of particles was carried out using a combination of static image analysis of particles and automated Raman micro-spectroscopy allowing the counting, size, shape and chemical composition of a large number of particles. The optimal combination was the 785 nm-laser with the gold coated microscope slide, which guaranteed a good Raman signal for the fingerprint region (1400 – 600 cm^{-1}), allowing the identification of the most common polymers found in the marine environment (the "Big six"). The novelty of this study was also that spectra were processed with an algorithm programmed to remove the Raman spectral background in a similar way for all of the spectra while keeping the analytical signal intact. Spectral extraction and identification were achieved using the SIMPLISMA algorithm model, which was modified to automate data processing. This analytical approach allowed a fast characterization and identification of a large number of microplastics particles, even when multiple polymers were combined.

MOPC10

Investigation of sorption properties and sorption kinetics of organic micropollutants onto microplastic particles

M. Maier, Eberhard Karls Universität Tübingen / Center for Applied Geosciences; S. Seidensticker, Center for Applied Geosciences; H. Ruegner, M. Finkel, Eberhard Karls Universität Tübingen / Center for Applied Geosciences; C. Zarfl, University of Tuebingen / Center for Applied Geosciences; P. Grathwohl, Eberhard Karls Universität Tübingen / Hydrogeochemistry Center for Applied Geosciences

For several years now, the pollution of aquatic ecosystems with microplastic particles, i.e. particles smaller than 1 mm, has been considered as a cause of rising concern due to their ubiquitous detection in the environment, their strong sorption capacity and their potential effects on all organisms along the food chain. Besides likely impairments of organisms due to the mere plastic material, microplastic particles are also suspected to act as vectors for contaminant transport. However, their function as pollutant carriers, which depends on material characteristics (e.g. plastic type and shape) but also on the substance properties, is still under discussion. In order to clarify this issue, sorption of six selected organic micropollutants onto different types of microplastics (particles, powders, fibres) is studied in batch experiments on equilibrium sorption and sorption kinetics. Additional sorption experiments are performed in dynamic bench-scale approaches simulating natural flow conditions in water bodies to close the gap between laboratory data and the environment. Diffusion limited sorptive uptake is mathematically described using analytical solutions for film diffusion and intraparticle diffusion which are the predominant processes in regulating sorption of hydrophobic organic contaminants. Additionally, experimental results are simulated by a numerical model using data and parameter values from analytical fits. Our results from batch experiments indicate non-linear sorption behaviour with partitioning coefficients in the same order of magnitude as given in the literature for organic pollutants and PE, e.g. derived log K_d-values for phenanthrene (Phe) are 3.76 and 4.21 L kg^{-1} for PE spherules and particles extracted from commercial facial cleaning products (peeling particles), respectively. Apparent diffusion coefficients for Phe obtained from intraparticle diffusion were in the order of 10^{-14} and 10^{-11} cm^2 s^{-1}, respectively, whereas the rate constants for film diffusion were in the range of 10^{-3} s^{-1} for peeling particles and 10^{-7} s^{-1} for spherules. Numerical model simulations resulted in water film thicknesses of 1 to 100 μm. These data indicate that the kinetic uptake of phenanthrene into spherules is mainly determined by intraparticle diffusion (possibly due to incomplete wetting) while for the peeling particles a strong influence of film diffusion at early time points and of intraparticle diffusion at later time points could be observed.

MOPC11

Investigation of adsorption behaviour of selected hydrophobic pollutants on polyethylene from different origin in different sizes

K. Sakaguchi-Soeder, TU Darmstadt / Material Flow Management and Resource Economy; M. Gottschling, TU Darmstadt; L. Schebek, TU Darmstadt / Material Flow Management and Resource Economy

Plastic wastes entered in the marine environment become brittle and fragmented into small pieces. These secondary microplastics (MPs) as well as primary MPs, which are manufactured to be of a microscopic size, are hardly mineralized in the environment. Thus, MPs are accumulated in the ocean and available to marine organisms. Toxic plastic additives can leach out of MPs. Persistent organic pollutants (POPs) or metals in the ocean have shown to adsorb onto and to be enriched on a surface of MPs. Microplastics in the ocean, thus, carry toxic substances to marine organisms. In order to determine the ecotoxicological effects of MPs on marine organisms, it is necessary to understand adsorption/desorption behaviour of pollutants on the surface of MPs. A series of batch experiments are in execution to study adsorption behaviour of four different PAHs on low-density polyethylene (LDPE). Specifically, we look into the influence of the polymer size and plastic additives on the adsorption behaviour of the PAHs. The LDPE used for our study varies in size (5 mm, 1.500 μm and 1.000 μm). In addition, LDPE derived from different origins (virgin pellets, pellets with additives, post-consumer product) is investigated. The progress of the adsorption is controlled using High Performance Liquid Chromatography (HPLC). The HPLC methods were optimized for four PAHs, namely naphthalene, fluoranthene, phenanthrene, benzo(a)pyrene. Freundlich adsorption isotherm is applied to derive polymer-water partitioning coefficients. As a preliminary test, adsorption of fluoranthene, a 4-ring PAH (log Kow 5,33, water solubility 0,26 mg/L) on LDPE derived from a post-consumer product was investigated. These artificially produced LDPE microplastics (0,02 g) are placed in batch reactors with fluoranthene dissolved in water with different concentrations (500, 1.000 and 2.000 μg/L). The first results showed the equilibrium was reached within 40 days and the maximum amount of fluoranthene adsorbed onto the LDPE was determined to be 14.000 μg/g-LDPE.

First evidence of microplastics in the African Great Lakes: Recovery from Lake Victoria Nile perch and Nile tilapia

F.J. Biginagwa, Sokoine University of Agriculture / Department of Biological Sciences; B.S. Mayoma, Mtwara District Council / Department of Livestock and Fisheries Development; Y. Shashoua, The National Museum of Denmark; K. Syberg, Roskilde University / Department of Environmental Social and Spatial Change; F. Khan, Roskilde University / ENSPAC

Microplastic contamination in the African Great Lakes is currently unreported, and compared to other regions of the world little is known about the occurrence of microplastics in African waters and their fauna. The present study was conducted in the Mwanza region of Tanzania, located on the Southern shore of Lake Victoria. The gastrointestinal tracts of locally fished Nile perch (*Lates niloticus*) and Nile tilapia (*Oreochromis niloticus*) were examined for plastics. Plastics were confirmed in 20% of fish from each species by Attenuated Total Reflectance Fourier Transform Infrared (ATR-FTIR) spectroscopy. A variety of polymer types were identified with likely sources being urban waste and consumer use. Although further research is required to fully assess the impact of plastic pollution in this region, our study is the first to report the presence of microplastics in Africa's Great lakes and within the fish species that inhabit them.

MOPC13

Chemical toxicity of virgin microplastics affects fertilization and larval development of sea urchins

C. Martinez-Gomez, M. Gomariz, Instituto Español de Oceanografia / Marine Contamination and Biological Effects; V. León, Instituto Español de Oceanografia / Centro Oceanográfico de Murcia; D. Vethaak, DELTARES / Marine and Coastal systems

Earlier studies have suggested that virgin microplastics (MPs) used in exposure experiments could be contaminated with unknown chemicals which can leach out into the medium during exposures contributing to toxic effects. In this study the toxicity of two polymeric materials and their elutriates was tested using the sea urchin embryo test (SET). Pre-embryos of the sea urchin *Paracentrotus lividus* were exposed for 48 hours to direct, aged and leaching solutions of two types of MPs at three different concentrations: virgins microspheres of fluorescent polystyrene (PS) (10^3, 10^4 and 10^5 particles/mL) and virgin granules of high density polyethylene (HDPE) (0.005, 0.5 and 5 g/L). Aged solutions were exposed for 30 days to natural ambient conditions of air, light and temperature. Leaching solutions were obtained after filtering (0.22 µm) the solutions previously stored for 30 days under non-air and dark conditions at ambient temperature. After the exposure of pre-embryos, the percentage of larval abnormalities and larval growth were determined and compared to the control. Overall, toxic effects on the embryonic development and the larval growth of the sea urchin were found in all the treatments (direct, aged and leaching solutions) of both polymeric materials compared with the control. Furthermore, highest toxicity (% abnormalities and reduction of the larval growth > 50 %) was found after exposure to the lowest concentrations of the leaching solutions also for both types of polymeric materials. MPs ingestion was observed in the gastric cavity of the larvaes in a concentration-dependent manner, but not in a toxicity dependent manner. These findings demonstrate that virgin MPs leach unknown chemicals, e.g. additives or residual and toxic monomers, which are mainly responsible for the observed toxicity. The results of this study warrant further research and might have potentially important consequences for the interpretation of data derived from aquatic toxicity studies with (virgin) micro and nanoplastics and their extrapolation to field conditions. **Acknowledgement -** This work has been supported by IMPACTA project and by the CleanSea project, part of the European Union Seventh Framework Programme (FP7/2007-2013), under grant agreement n° 308370.

Habitat improvement in the agricultural landscape to assure the protection goal "biodiversity" (PC)

TUPC01

Development of a risk mitigation toolbox dedicated to pesticides in farmland in Europe: expected benefits for environmental protection and biodiversity and recommendations

A. Alix, Dow Agrosciences / Risk Management; K. Knauer, Federal Office for Agriculture / Section Plant Protection Products; V. Poulsen, ANSES / French Agency for Food Environmental and Occupational Health and Safety; M. Streloke, BVL / Plant Protection Products; B. Golla, JKI

The registration process for Plant Protection Products (PPP) or pesticides in agriculture relies on a preliminary evaluation of the risks they may pose to human health and the environment in the farmland. Risk mitigation measures may accompany the registration in providing detailed conditions of use to reduce exposure of non-target organisms and /or residue transfer in environmental compartment to acceptable levels and thus reach the expected protection goals. These mitigation measures range from the use of special application equipment to the implementation of landscape features such as buffer strips or recovery areas, which may be recommended on product's labelling. Some of these measures are also recommended in the European Common Agriculture Policy (CAP). A two stage workshop was organized to inventory the knowledge and experience in risk mitigation measures throughout the EU. The workshop invited risk assessors and risk managers industry, academia and agronomical advisors/extension services within 21 European countries to develop a toolbox of risk mitigation measures designed for the more flexible management and use of pesticides for agricultural purposes, and thus contribute to promoting policy and practice harmonization within Europe. The workshop focused on a broad range of environmental risks: wildlife including vertebrates and invertebrates, flora and microorganisms, biodiversity as well as surface- and groundwater quality, identified as protection goals in the European regulation on pesticides. This poster will present the toolbox developed and illustrate the expected benefits of the measures recommended for the protection of wildlife in agro ecosystem.

TUPC02

INVENTORY OF POTENTIAL ECOLOGICAL FOCUS AREAS IN AGRICULTURAL LANDSCAPES IN THE CONTEXT OF THE COMMON AGRICULTURAL POLICY REFORM

S. Englhart, M. Stängel, RSS Remote Sensing Solutions GmbH; A. Kroll, JKI / Institute for Strategies and Technology Assessment; B. Golla, JKI; J. Franke, Remote Sensing Solutions GmbH

According to the EU Commission, direct payments to farmers should be linked to ecological measures (CAP Greening). One component is the establishment of ecological focus areas (EFA) on the agricultural field. The aim of this study is to identify site-specific marginal areas within agricultural sites, which could be designated as potential ecological focus areas from an agronomic and landscape-ecological perspective. These areas are mainly characterized by perennial abiotic factors that cause plant stress (reduced water capacity, soil properties etc.) These small-scale growing anomalies were inventoried based on multi-spectral satellite imagery. Two different vegetation indices (NDVI, NREVI) were calculated on the basis of high-resolution RapidEye imagery in order to assess marginal sites within predefined field blocks. Object-based hierarchical classification of site-specific areas within a field block was conducted based on a robust statistical approach by comparing sub-object vegetation indices across the entire block. Sub-object statistics of vegetation indices were compared to those of the field block in order to derive relative deviations. Four different classes were then defined using relative deviation threshold values based on overall mean field block indices values. The resulting processing method proofed to be transferable to RapidEye scenes from different acquisitions dates. The identified areas were integrated in a Cadastre of potential EFAs and can be used by decision makers and stakeholders responsible for protecting and increasing agro-biodiversity (e.g. inventory of EFA, sustainable plant protection strategies, integrated pest management and risk management).

TUPC03

Protection of wild pollinators in pesticide risk assessment and management

R. Bereswill, Ecotox Consult; C. Bruehl, University of Landau, Institute for Environmental Sciences / Institute for Environmental Sciences; M. Meller, J. Nickel, ecotox consult, Dr Michael Meller ecotoxicological, consulting service; P. Stahlschmidt, University of Koblenz-Landau / Institute for Environmental Sciences; D. Suessenbach, UBA / Department IV plant protection products; C.J. Topping, Aarhus University / Department of Bioscience; P. Uhl, University of Koblenz-Landau / Institute for Environmental Sciences

Latest research on biodiversity in agricultural landscapes suggests that pollinating insects (especially wild bees and butterflies) are not sufficiently protected from the effects of plant protection products under the current risk assessment and risk management schemes. This might be the result of uncertainties in existing risk assessment practice. Currently, only honey bees are tested in risk assessment and are assumed to be representative for all bee species. Other taxa of pollinators are not incorporated, so far. Moreover, the spatial dynamics of mobile arthropods (such as wild pollinators) which move between non-target area (e.g. buffer strip) and target area (field) are not taken into account. Becoming aware of these uncertainties European Food Safety Authority (EFSA) published a scientific opinion in 2015 addressing the state of the science on risk assessment of plant protection products for non-target arthropods. The preparation of a respective EFSA guideline is planned for 2017. The research and development project Z 6 – 93 401/60 (FKZ: 3715 64 409 0), funded by the German Federal Environment Agency (Umweltbundesamt), aims to provide a basis for the revision of risk assessment and risk management schemes for the protection of wild pollinators from the effects of plant protection products. As part of this project, the current EFSA scientific opinions and draft guidance for the risk assessment of bees and terrestrial non-target arthropods will be reviewed for deficits with respect to the protection of wild pollinators. Furthermore, data on ecology, exposure and toxicological sensitivity of wild pollinators will be collected. Based on this data, ecologically tolerable thresholds will be derived and the relative sensitivity of different groups of wild pollinators in crop-specific landscape scenarios will be determined. Using this information, criteria for the risk assessment scheme on wild pollinating insects as well as recommendations for the improvement of potential risk management options will be developed. The regulatory background and the aim of the project as well as first findings are presented in this poster.

TUPC04

Ecological enhancement of agricultural land in the Upper Rhine Plain

R. Oppermann, Institute for Agro-ecology and Biodiversity (IFAB), Böcklinstr. 27, D-68163 Mannheim, Germany; M. Blank, Bayer

The project "Ecological enhancement of agricultural land in the Upper Rhine Plain" aims to find a broadly implementable way to increase the biodiversity and especially to promote and support wild pollinators and honey bees in intensively used agricultural landscapes. Therefore, a matrix of different enhancement measures like flower strips or bee banks was implemented in the intensive farmland in order to increase species richness and populations of pollinators and other farmland wildlife. A mix of annual and perennial flowering plots was used, which are manageable by the farmers in their work routine and flexibly integratable in the farmland regime. Over a time period of five years (2010 - 2014) changes in landscape structure, pollinator biodiversity and ecological parameters of arable fields were recorded. After a baseline survey in 2010, flower strips and flower fields are cultivated on 10 % of arable land within 50 ha study areas on two farms since 2011 ongoing, which are complemented by unmodified control areas of the same size. Wild bees and butterflies were sampled on flowering plots in the enhancement areas and on flower-rich structures in the control areas. Wood blocks with nesting tubes were installed to facilitate sampling of the wild bee species, and bee banks (mounds of bare soil) were created in the enhancement areas as nesting structures for ground-nesting bees. Autumn and spring sowing was carried out and the seed mixtures were adapted year by year according to the results obtained regarding an overall good variability of plant species and flowering periods, their attractiveness for pollinators, their ability to suppress undesired weeds, and their affordability numbers increased greatly on the enhancement plots. The results show that both, a variety of different flower strips/fields and a long continuity of the measures contribute to an increase of species numbers and abundance of the species. Further results regarding species composition, effects on butterflies, seed mix composition and management options are shown and discussed.To sum up, the results indicate that a broad implementation of the approach could greatly contribute to the promotion of pollinators and help to increase the biodiversity in intensive arable regions.

TUPC05

Plant Protection Products: Risk Mitigation Measures for Birds

R. Gauch; O. Daniel, Agroscope / Institute for Plant Production Sciences IPS

To ensure a safe use, measures can be disposed along with the authorisation of plant protection products to mitigate the risk to non-target organisms. Such risk mitigation measures (RMM) should be quantifiable and generally applicable to a broad range of crops. For off-field non-target organisms, the risk can easily be mitigated by applying buffer zones to surface waters or biotopes, for example. For non-target organisms occurring in the field it is somewhat more challenging to find suitable RMM. Currently applied RMM for birds in countries in and outside the European Union are presented. Further possible RMM for birds are extracted from open literature and expert questioning. The pros and cons of the RMM are evaluated and discussed regarding their potential to be used within the regulation of plant protection products.

TUPC06

Evaluation of ecological sustainability of Italian rice cultivation: identification of regulation for environmental protection and analysis of existing voluntary or mandatory agri-environment measures

V. Zaffagnini, C. Vaj, M. Bradascio, Dow AgroSciences Italia s.r.l.; E. Di Tullio, NOMISMA; S. Cerioli, M. Tabacchi, ValOryza; C. Panigada, A. Finizio, University Milano - Bicocca / Department of Environmental and Lanscape Sciences and Earth Sciences

Italy is the European leading rice producer (accounting for 48% of the EU production quantities) and exporter (representing 38% of the EU rice exports). Rice cropping is almost exclusively located in the Po Valley (Piemonte and Lombardia account for 94% of the national production). In Italy rice is not only a key economic resource, but it has also a high value as environmental system. Interaction between rice cropping and the surrounding environment is very strong, by generating a real water agro-ecosystem since paddy fields enhance biodiversity and represent a core patch in agricultural landscapes. The interest of public opinion towards environmental protection and human safety is continuously growing and the European and national decision makers progressively integrated those elements in their regulatory guidance. The implemented processes descending from this regulatory system affect the agricultural practices, in the form of obligations and provisions the farmers have to follow when paddy-fields are located in protected natural areas (e.g. national and regional natural parks and reserves or sites belonging to the European Natura 2000 Network) or in the form of voluntary measures of Rural Development Plan (RDP) defined by the Common Agricultural Policy (CAP). In the presented work the authors identify these measures, which guarantee protection of environment and biodiversity as well as the promotion of environmental friendly agricultural practices, and assess their adoption by the Italian rice-growers. The diffusion of these measures and practices in terms of involved rice surface is identified with a geo-referenced analysis using GIS. As a first result it is possible to assess the strong link existing between the Italian rice cultivation and the protected natural areas. As a second step, the study highlights which are the main environmentally friendly practices and measures of the 2007-2013 Rural Development Plan (RDP) the farmers adopt, with their proportion in the main Italian Regions where rice is cultivated. Some considerations about the combination of measures and the relation of the selected measures with eventual mandatory prescriptions in protected natural areas are done. All the results are given also using cartographic methods, which enables the communication of the results in a spatial explicit way. The possibility of using this study as a methodological support to stakeholders and local territorial decision makers is also discussed.

TUPC07
Swiss agri-environmental indicators: Development of pesticide usage and aquatic risks over five years
L. de Baan, Agroscope / Institute for Plant Production Sciences IPS; R. Gauch; O. Daniel, Agroscope / Institute for Plant Production Sciences IPS
In Switzerland, a set of agri-environmental indicators are calculated on a yearly basis to monitor the effects of agriculture on the environment. Two indicators are directed towards pesticides (i.e. plant protection products): (1) indicator on pesticide usage and (2) indicator on aquatic risks. These national indicators can serve as important data source for better understanding the exposure of agricultural landscapes to pesticides. In this poster, we present the development of these indicators over the first five years of this agri-environmental monitoring program (2009-2013). The input data for these agri-environmental indicators are collected through a network of more than 300 reference farms. These farms annually provide their field calendars, i.e. they report for each pesticide application the applied product, crops, date and amount of applied pesticide. Based on this data, several key figures are calculated for the indicator on pesticide usage, such as number of interventions and amount of active ingredients applied per crop group. For the indicator on aquatic risks, the pesticide usage is fed into the model SYNOPS (Gutsche & Strassemeyer, 2007), which calculates the fate and the final “predicted environmental concentration” (PEC) in edge-of-field surface waters over a cropping season. The PEC value is then compared to the ecotoxicity data of each active ingredient and the risk is expressed as Exposure-Toxicity-Ratio (ETR). Risks are then aggregated over different taxonomic groups (water plants, invertebrates and vertebrates) and over entire spray-application-sequences. The risks to aquatic environments are finally displayed as aggregated values per crop group. For the indicator of pesticide usage, there are large differences between crop groups, but inter-annual variation is rather small. For the indicator of aquatic risks, there are large variations between crop groups, within crop-groups and also between years. These agri-environmental indicators provide a key information for monitoring the long-term development of the environmental impacts of the current agricultural praxis in Switzerland and help to evaluate policy instrument to reduce these impacts. In addition, the indicators can help to understand and visualize the pesticide-intensity of different crop groups within agricultural landscapes.

Oil and Gas Extraction: Ecological Effects and Science-Based Management (PC)

TUPC08
AN ECOLOGICAL APPROACH TO OIL SANDS
D. Nunes Cardoso, CESAM, University of Aveiro / Department of Biology and CESAM   Centre for Environmental and Marine Studies; J. Pestana, CESAM & University of Aveiro / Department of Biology and CESAM; S.F. Goncalves, Department of Biology & CESAM - University of Aveiro / Department of Biology   CESAM; F. Wrona, University of Victoria / Department of Geography; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; S. Loureiro, Universidade de Aveiro / Biology
The oil sands deposits of Athabasca River area, in northern Alberta (Canada), are the world’s largest oil reserves with several specific and special characteristics that make them a special case study, having both a high potential for expanding hydrocarbon extraction and also a region to assess associated cumulative environmental impacts. A key issue in the oil sands area is discrimination natural versus anthropogenic sources of oil sands related with contamination of surface and groundwater and the effects on aquatic ecosystem structure and function. The lower Athabasca River and its tributaries flow through natural bitumen deposits and consequently, it is a scientific challenge to distinguish between types and levels of hydrocarbon-associated contaminants that occur naturally in surface and groundwater from those arising from anthropogenic activities such as oil sands mining and upgrading of oil. The main objective of this study was thus to evaluate the acute and chronic ecotoxicological effects associated with the slumping of river bank material that is comprised of oil sands deposit that naturally enters the river systems through fluvial processes. For that, ecotoxicological tests were conducted using parental geological material collected from the river banks near the oil exploitation area (Alberta, Canada), in 4 different locations in 3 rivers. Samples differ each other mainly in terms of texture and proportional bitumen content due to the differences in the specific geological formations in each river basin. The solid samples (treated as soils), sediment and water-based exposure tests were carried out, using standardized ecotoxicological tests with representative terrestrial (*Folsomia candida*) and aquatic (*Daphnia magna*, *Physa acuta* and *Chironomus riparius)* organisms. Preliminary results confirmed that a suite of methodologies were needed to derive an accurate assessment of effects due to background presence of oil sands compounds. The use of both soil and aquatic organisms provided complementary knowledge on the possible ecotoxicological effects related to exposure to oil sands materials arising from bank erosion-related processes. From the results of bioassays carried out, different patterns of toxicity were observed considering the different samples’ collection areas and types of slumping material (content in bitumen), suggesting that the geological context of the area must be taken into consideration when analysing assessing ecological effects.

TUPC09
Endocrine disrupting potentials of crude petroleum related PAHs and their alkylated analogues
S. Lee, Seoul National University / School of Public Health; S. Hong, Seoul National University / School of Earth and Environmental Sciences; X. Liu, C. Kim, K. Noh, Seoul National University / School of Public Health; D. Jung, Seoul National School / Institute of Health and Environment; U. Yim, Korea Institute of Ocean Science & Technology / Oil and POPs research group; W. Shim, Korea Institute of Ocean Science and Technology / Oil and POPs research group; J. Khim, Seoul National University / School of Earth and Environmental Sciences; J. Giesy, University of Saskatchewan / Department of Veterinary and Biomedical Sciences and Toxicology Centre; K. Choi, Seoul National University / School of Public Health
Polycyclic aromatic hydrocarbons (PAHs) and alkylated PAHs are major component of crude petroleum. Spilled crude petroleum undergo weathering process and composition of alkylated PAHs could be changed. It is speculated that PAHs have endocrine disrupting potential by affecting sex hormones, and that such potential differs according to the type and alkylation status of the PAH. In this study, therefore, we evaluated the endocrine disrupting potential of five major PAHs of crude petroleum (naphthalene, fluorine, dibenzothiophene, phenanthrene and chrysene) and their alkylated analogues by MVLN-*luc* and H295R *in vitro* assay system. In MVLN-*luc* bioassay, ER binding potency of 11 PAHs were observed among total 30 tested PAHs. Among them, phenanathrene and its alkylated analogues generally showed greater potency (range of %-E2max from 1.6% to 47.3%) but the greatest ER binding potency was observed in 1-methylchrysene (101.4%). In H295R bioassay, significant increase in sex steroid hormones synthesis was observed in 20 PAHs. Although effect of alkylation on sex hormone synthesis could not be explained simply, different endocrine disrupting potential in alkylated analogues were observed. In this study, we observed steroidogenesis mediated endocrine disrupting potential of unsubstituted and alkylated PAHs rather than disruption via the ER binding pathway. This implies that steroidogenesis is important as a major pathway of endocrine disruption induced by PAHs. Therefore, steroidogenesis pathway should not be ruled out of the investigation for endocrine disruption in the oil spill site or PAH contaminated site. This work was supported by Korean Ministry of Oceans and Fisheries Project PM56951.

TUPC10
Quantifying the Role of Photochemical Processes in Aquatic Risk Assessment of Petroleum Substances
T. Parkerton, ExxonMobil Biomedical Sciences Inc. / Toxicology   Environmental Science; A.D. Redman, Exxon Mobil Biomedical Sciences / Toxicology and Environment Science Division
Petroleum substances may contain polyaromatic hydrocarbons (PAHs) that interact with sunlight. These interactions can increase hazard, as a result of photo-enhanced toxicity, while reducing exposure, as a result of direct and indirect photodegradation processes. Currently, photochemical processes are not included in the PETRORISK modelling framework that has been developed and applied for conducting environmental risk assessments of petroleum substances as required

under the EU chemicals legislation (i.e. REACH). To quantitatively assess the role of light interactions on hazard and exposure assessment, available photodegradation and phototoxicity data were used to parameterize hazard and EUSES multimedia exposure models for a representative 3-ring (anthracene), two 4-ring (pyrene, fluoranthene) and 5-ring (benzo[a]pyrene) PAH. These models were then used to calculate risk quotients to aquatic life for various generic, regional exposure scenarios representing a range of sunlight exposures during winter and summer in both nutrient poor and rich natural waters. Risk quotients from these scenarios were then compared to the default case that ignored light. Results indicated that photodegradation rates were faster than biodegradation rates and of a similar magnitude for all PAHs except fluoranthene which had a ten-fold slower rate. Analysis of phototoxicity data indicated all PAHs exhibited a similar species sensitivity distribution when normalized to the combined PAH and daily ultraviolet exposure metric of micro W cm^{-2} micro g L^{-1}. Resulting risk quotients for each PAH and scenario that included sunlight were similar to or lower than the no light case since the predicted enhancement in toxicity resulting from light exposure was effectively mitigated by reduced PAH water exposure due to photodegradation. This study indicates that neglecting light interactions in generic risk assessment for PAH containing petroleum substances does not preclude effective chemical management since risk quotients are not increased.

TUPC11
Integrated Environmental Mapping and Monitoring
I. Nilssen, Statoil ASA and Norwegian University of Science and Technology / Environmental Technology; G. Johnsen, Norwegian University of Science and Technology / Department of Biology; T.W. Nattkemper, Bielefeld University / Biodata Mining Group; V. Hepsø, Statoil ASA and Norwegian University of Science and Technology / Environmental Technology
Technology development, including sensors and sensor platforms, has enabled a more holistic approach to environmental mapping and monitoring. To be able to meet the environmental challenges, interdisciplinary communication and collaboration is required. As all humans share special cognitive skills in detecting and classifying objects of interest and movement with their visual system, use of imaging technology in integrated environmental monitoring have the ability of enhancing interdisciplinary communication and collaboration. To enable an extended utilisation of images in environmental monitoring, several issues still have to be further developed. This will be outlined in the presentation. However, combined use of images with other sensor data will enhance the information and facilitate improved communication and collaboration, not only between scientific disciplines but also between science and authorities and/or public in general. An interdisciplinary approach, where sensors and sensor platforms used are adjusted to purpose, can provide the flexibility needed for a knowledge driven and cost efficient environmental mapping and monitoring.

Sustainable use of Veterinary Pharmaceuticals on the territory and groundwater resources quality
A. Di Guardo, Universita degli Studi di Milano-Bicocca / Department of Earth and Environmental Sciences; A. Finizio, University Milano - Bicocca / Department of Environmental and Lanscape Sciences and Earth Sciences
Emerging contarninants such as Veterinary Pharmaceuticals (VP) are becoming of increasing concern as consequence of their potential negative environrnental inpact. Due to their high consumption and the increasingly presence of VPs residues in water, the scientific community has become increasingly interested in investigating the effects ofthese chemicals on aquatic environments, both in groundwater and surface water systems. \nThis paper aims to address the problem of how to reach a sustainable use of VPs in the Lombardy area (North of Italy) and try to fill the gap of knowledge on how to implement appropriate risk mitigation measures on the territory to protect groundwater resources quality.\nAn exixting tool called VULPES has been used to help to plan and manage VPs use in\na sustainable way in the Lombardia Region. VULPES is a GIS-based decision support system enabling local authorities to assess the aquifer vulnerability to leaching of chemical substances by linking predictive exposure models with regional and local environmental scenarios (using GIS systems).\nScenarios will be developed using realistic characteristics of the territory (climate, soil, crop parameters, irrigation) the realistic usage of VPs and the realistic livestock practices (i.e. manure management). To achieve this objective we propose a guideline which aims to collect, organize and link information, database or tools that are already available in Lombardy Region, but that were in some way spread and scattered. In addition other relevant information has been collected from available scientific literature (predictive models, physical chemical properties ofVPs) or generated (capillary collection of information about the use of VPs).\nAnother outcome of the guideline is to raise environmental awareness of decision makers and farmers about the use of VPs in intensive livestock conditions.

Towards a model- and landscape-based regulatory aquatic risk assessment of pesticides: state-of-the-art and recommendations for improving fate and effect models
A. Focks, M. ter Horst, Alterra, Wageningen University and Research Centre / Environmental Risk Assessment Team; P.I. Adriaanse, Alterra Wageningen University and Research Centre / ERA team; E. van den Berg, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team; J. Boesten, Alterra / ERA team; A. Rico, Wageningen University / Environmental Risk Assessment Team; H. Baveco, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team; P. van den Brink, Alterra and Wageningen University / Aquatic Ecology and Water Quality Management Group; L. Wipfler, Alterra Wageningen UR
Ecological modelling approaches have been recently implemented in Environmental Risk Assessment (ERA) to overcome some of the limitations of experiment-based effects assessments, namely the extrapolation across different temporal and spatial scales, and the extrapolation across different levels of biological and environmental complexity (Schmolke et al., 2010; Forbes et al., 2011). In some early examples, ecological modelling approaches were applied to answer questions regarding the possibility for propagated effects and recovery of aquatic and terrestrial populations in a spatially explicit environment context. In most of these studies, exposure assessments were performed using standard exposure scenarios and linked to population models that used ecological scenarios not necessarily matching those used in the exposure assessment. Recently, EFSA proposed to define and use environmental scenarios including ecological and exposure aspects as an umbrella under which consistent definitions of spatial and temporal boundary conditions and input parameter ranges can be collected. The idea of the definition of environmental scenarios is that the scenario selection procedures for the ecological and exposure scenarios and their parameterisation are based on common principles, allowing an integrated evaluation of fate and effect modelling results for regulatory ERA. In this presentation, we will give examples of early studies that integrate fate and effect modelling approaches at different landscape scales for aquatic (eco-)systems (Van den Brink et al., 2007; Galic et al., 2012, 2013; Focks et al., 2014, Baveco et al., 2014), and summarise a proposal for a structured approach to define ecological scenarios (Rico et al., 2015). Furthermore, we will summarise the state-of-the-art of fate models for the aquatic environment with respect to their applicability in ERA, balancing between the precision of model simulations, as needed for risk assessment, and the incorporation of large-scale systems, as required for more ecologically relevant landscape evaluations. In this presentation, the consequences of the development of ecological scenarios for the selection procedures for exposure scenarios and for the scale of the fate models to be used are identified. In addition, we will summarize the main challenges resulting from coupling fate and effect modelling approaches for pesticide registration and will propose some possible solutions as a way forward.

TUPC16
Validation of the GIS-based model SYNOPS to assess environmental risk of pesticides using four years of monitoring data in the small Lamme catchment
J. Strassemeyer, ral Research Centre for Cultivated Plants / Institute for Strategies and Technology Assessment; A.R. Dominic, Julius Kühn-Institut, Federal Research Centre for Cultivated Plants / Institute for Strategies and Technology Assessment; B. Golla, JKI; S. Lorenz, M. Stähler, A. Süß, Julius Kühn-Institut, Federal Research Centre for Cultivated Plants / Institute for Ecological Chemistry Plant Analysis and Stored Product Protection; J. Tecklenburg, Julius Kühn-Institut, Federal Research Centre for Cultivated Plants / Institute for Strategies and Technology Assessment
The use of pesticides in agriculture causes environmental risks which must be managed carefully. On the EU level, specific Directives and National Action Plans (NAPs) have set reduction of agriculture-related pollution on the agenda. Within the German NAP, the risk indicator model SYNOPS-GIS is applied for regional risk analysis and assessment of the effects of mitigation measures. SYNOPS-GIS assesses the risk of chemical plant protection products for aquatic and terrestrial organisms. It combines data on pesticide usage with their application conditions and their inherent properties. The predicted environmental concentration of active substances is calculated on a daily basis for surface waters considering crop interception, spray drift, surface run-off and drainage. The current version of SYNOPS-GIS incorporates sub-models which are used in the European registration process, namely PRZM for the run-off assessments and VFSMOD to assess the filtering potential of buffer strips. The calculated daily environmental concentrations and the toxicity values for five aquatic reference species are used to express the risk as exposure-toxicity ratios. The risk due to multiple exposure of organisms to a variety of active substances is assessed with SYNOPS-GIS by risk addition according to the spatio-temporal concentration patterns of the active substances in the surface water. Monitoring data of pesticides in the small stream Lamme were used to validate this model approach. The upstream sub-catchment of the Lamme was part of a monitoring project conducted from 1995-1999. It is located in Lower Saxony (Germany) and includes eight fields of 109 ha. The total sub-catchment has an area of 194 ha and no settlements are located in the

catchment. The sample site is located 1.2 km downstream from the spring. The fields in the catchment were used by one farmer growing winter wheat, sugar beets and oilseed rape. All pesticide application events in the catchment were monitored. In addition weather data (precipitation, temperature) were measured and data on landscape structures (e.g. buffer zones, field margins), soil and slope were derived from detailed GIS datasets. Of the37 active substances applied over the time period of four years, 14 were detected in the weekly composite samples. These monitoring results are correlated with predicted concentrations of SYNOPS-GIS and the results are discussed.

Development and application of a modular landscape-scale vole model for pesticide risk assessment combining the models Xplicit and Polaris

T. Schad, Bayer CropScience / Environmental Modelling; M. Wang, WSC Scientific GmbH / Dept Efate Modelling; T. Preuss, Bayer CropScience / Environmental Modelling; S. Bub, Bayer CropScience

Recently, the potential of conducting landscape-level risk assessments has been discussed to predict potential effects of pesticides on non-target organisms at landscape scales (e.g. EFSA 2015a and b). This requires on one hand (i) to develop landscape model approaches, and on the other hand (ii) to develop scenarios fulfilling requirements of regulatory risk assessment and management. Landscape-scale modelling comes with a range of disciplines, ranging from modelling of environmental conditions, data and knowledge on land and farm management, exposure and efate modelling, ecological modelling, and in particular risk characterisation according to protection goals. All of these fields are in dynamic development and require specific knowledge. On this background, and due to the fact that a variety of very specific models often exist, we adapted a modular approach which allows combining individual model components using standardised interfaces. This not only allows to flexibly combine of models and to increase the level of complexity step by step in the risk assessment, but it also helps risk assessors to efficiently evaluate risk assessments, because once modules are validated they can be reused without the need of re-validation. In this respect, this approach also facilitates harmonisation. In a first implementation of this architecture we combine modules from a landscape-scale model (Xplicit; environmental conditions, land use/cover, PPP use, exposure, efate) with a vole model (Polaris), as well as modules for risk analysis. Due to its openness, it is straightforward to introduce e.g., new landscape data. This approach is used to analyse relationships between landscape characteristics (composition, structure, management, scales) and vole population dynamics, with and without pesticide use, in order to identify realistic worst-case scenarios for risk assessment (EFSA 2015c, Wang and Luttik 2013). In this poster we present details on the modular landscape modelling concept and its implementation for a vole risk assessment. We show that the model can flexibly be used at different scales and different risk assessment tiers (complexity level). In addition, we illustrate how the landscape-scale modelling approach can be used to identify which factors determine the level of susceptibility of populations.

Comparing observed and predicted honeybee nectar-foraging at landscape level

H. Baveco, A. Focks, Alterra Wageningen University and Research Centre / Environmental Risk Assessment Team; D. Belgers, Alterra Wageningen UR; J. Van der Steen, PRI Wageningen UR; J. Boesten, I. Roessink, Alterra / ERA team

We applied a landscape-level nectar foraging model using the spatial settings associated with a field experiment on honeybee foraging. The model calculates foraging behaviour based on energy balance of honeybee foragers for a single day in complex landscape mosaics. The hive population is assumed to select the resource patch with highest net energetic efficiency and to have perfect knowledge of its environment. By using real-world GIS data, including semi-natural elements such as field margins and buffer strips, present within a radius of several kilometres, the model can quantify foraging costs and yields in terms of energy for the specific field situation, and based on these calculations the amounts of nectar from the different fields and other nectar sources in the neighbourhood arriving at a bee hive. In the experiment a 1 ha flowering field of oilseed rape, was sprayed with a non-toxic tracer. After application, during the remainder of the day, bees were collected approximately every hour in the sprayed field and at the entrance of the two beehives situated next to the field. Tracer residues differed between field and hive collected samples hinting towards dilution at the hive or the presence of other yet unknown factors. We used the model to test several plausible explanations for the observed experimental results. In particular, the hypotheses were tested that either the presence of attractive alternative nectar sources in the wider landscape could have resulted in less than expected numbers of foragers visiting the crops, or that a large fraction of what were considered foragers were in fact apprentices, learning to practice their foraging skills. Vice versa, the experimental results helped to perform a reality check for the foraging model by comparing observed to simulated nectar concentrations. In particular, the assumption was tested that at any time, only a single, optimal, resource would be exploited.

TUPC19

A bug's eye view - quantifying pesticide heterogeneity at micro-scales needed to model non-target arthropod behaviour in orchards

J. Witton, University of York / Environment; G. Weyman, ADAMA Agricultural Solutions Ltd.; M. Reed, Chemicals Regulation Directorate; M. Pickering, M. Hodson, University of York / Environment Department; R. Ashauer, University of York / Environment

Pesticide exposure within fruit orchards has been widely studied, but rarely at more than one spatial scale; in addition it is usually undertaken in the context of human exposure. Here we take a different approach. We aim to quantify pesticide exposure at scales relevant to individual non-target arthropod behaviour. Such species are included in the regulatory risk assessment of pesticides, and may provide important ecosystem services. We assessed five spatial scales during a spray application of the fungicide penconazole in an apple orchard in the UK in August 2015 and used two residue analysis methods: pesticide extraction from apple leaves and analysis via GC-MS; and computer-based image analysis of pesticide deposition on water sensitive paper. We report residue levels focusing on the spatial scales most relevant to two non-target arthropod species widely used in both biocontrol and pesticide risk assessment: the green lacewing *Chrysoperla carnea*, and the predatory mite *Typhlodromus pyri*. In addition we evaluate the potential for water sensitive paper to be used in residue studies instead of cost- and time-intensive analytical techniques. Our results feed into a wider project to produce a model that predicts the population-level consequences of lethal and sub-lethal effects of pesticide exposure, including potential avoidance at the micro-scale, on the two non-target arthropod species.

Communicating research findings and uncertainties: Strategies, tools, and new platforms for environmental sciences (PC)

Contrasting public perception of pollution in a small European city and an East Asian megacity - the case of York versus Seoul

L.H. Youds, University of York / Environment

Around the world, a shift towards urbanisation is being realised. Currently, over 50% of the world's population live in cities and this is expected to increase to 66% by 2020. With higher rates of urbanisation come greater levels of pollution. In cities, this encompasses a diverse range of issues under noise, air, soil and water pollution themes. Pollution in cities is an important problem due to the effect that the variety of pollutants may have on human health and wellbeing and the health of the natural environment. The rate and extent of urbanisation varies considerably around the world, thus the extent and composition of pollution in different cities also display great variety. Urbanisation in Europe stands at 73.6%, whilst in some East Asian countries, such as South Korea and Japan, urbanisation stands at higher rates of 82.5 and 91.3%, respectively. Although the extent of urbanisation in both regions is not wildly variant, the above figures hide more interesting information on the significantly different historical development of European versus East Asian cities and the impact that these development trajectories have had on culture, public policy, economic structure, the environmental, social and physical characteristics of cities, and vice versa. This poster presents the findings of a comparative study of public opinion on pollution in a small European city (York, UK) and an East Asian megacity (Seoul, South Korea). The findings are presented within the context current pollution- and environment-related attitudes of citizens within each city and will include measures of: citizen engagement in the use of innovative technology and social media for monitoring personal exposure to pollutants; participation of citizens in public policy decision-making; and behavioural trends in terms of limiting personal exposure to pollutants and reducing environmental footprints. In addition, the historical developmental trajectory of each city will be discussed and the possible impact that culture, economic development, rate of urbanisation over time and governance may have on the varying attitudes and opinions of each city's public. The findings of this study have significant implications for beginning to understand how different cities digest, value and respond to information on pollution problems in substantially different contexts.

WEPC02

Uncertainty avoidance in environmental risk assessment - current guidance and future challenges

A. Hunka, Halmstad University / Biological and Environmental Systems; M. Meli, ADAMA; A. Palmqvist, Roskilde University / Department of Environmental Social and Spatial Change; P. Thorbek, Syngenta / Environmetal Safety; S. Waara, Halmstad University; V. Forbes, University of Minnesota / Ecology Evolution Behavior

Uncertainty estimations are inherently built into any scientific process, not excluding environmental risk assessment (ERA). Although usually hidden behind safety factors and policy decisions, in recent years, with the development of new assessment methods, uncertainty has become more explicit. Despite this, most people, including risk assessors and managers, avoid uncertainty and often display uncertainty-averse behaviours when making decisions. Uncertainty avoidance describes the level of tolerance of uncertainty and ambiguity, where choices are biased towards assigning greater weight to information about uncertainty in comparison to the rest of available data. As to date, we know little about the social and psychological factors contributing to that phenomenon. The aim of our study is to systematically analyse different ways of addressing uncertainty in ERA, using existing (or proposed) guidance and legal frameworks for ERA, focusing especially on uncertainty perception and sources of uncertainty beyond statistical estimations. We identified gaps, challenges and suggested ways to incorporate, so far overlooked, psychological factors, especially uncertainty avoidance, into risk management. Our preliminary results show that both perceived uncertainty and uncertainty avoidance have been so far overlooked in ERA regulations. The most general decision-making guidance, the precautionary principle refers to "unacceptable risks" and scientific uncertainty, but leaves them in the domain of political responsibility. Currently, only ESFA's draft guidance document explicitly acknowledges perceived uncertainty in ERA. Whereas uncertainty analysis is a well-established part of ERA guidance documents, a systematic, empirical analysis of perceived uncertainty in ERA and especially of uncertainty avoidance is lacking. Existing probabilistic models incorporating uncertainty in ERA do not take into account individual or social variables. Still, the awareness of these kinds of influences on decision-making processes is growing. To keep ERA ready for emerging risks, it is not enough to develop new assessment methods and more accurate predictions. Underlying reasons for uncertainty avoidance need to be addressed to facilitate informed risk communication.

WEPC03

Accounting for Environmental Recovery in Risk Assessment and Management

S. Deacon, ENVIRON UK Ltd; A.E. Bartram, Ramboll Environ / Product Safety Ecology and Sediment Management; N.J. Eury, Ramboll Environ UK Ltd

The Energy Institute (London, UK) has developed a guide for risk assessors to determine the duration of environmental recovery following major accidents to the environment. The guide is designed to support site safety reporting for the UK Control of Major Accident Hazard (COMAH) Regulations, which implements the SEVESO Directive (2012/18/EU). The information gathered on environmental recovery may also have wider uses for predicting recovery in damage and compensatory assessments (Environmental Liability Directive 2004/35/EC) and evaluating risks as part of contaminated site assessments. The guide is currently undergoing final sign off for publication in 2016. The aim is to provide easy-to-use guidance for defining environmental recovery based on major accident scenarios for releases of SEVESO substances, including petroleum based products. The guide provides a framework for the selection of appropriate recovery criteria for a range of temperate habitats using typical release scenarios for hazardous substances. The primary audience for the guide will be managers and their advisors responsible for the preparation of Site Safety Reports by establishment of risk screening for refineries and chemical production facilities together with storage terminals. The approach includes a review of published literature on habitat and species recovery from accidental spills. In parallel, the physico-chemical properties, environmental fate and ecotoxicity of chemicals captured by COMAH/SEVESO III were evaluated to identify persistent, bioaccumulative and toxic (PBT) substances with the potential for longer-term impacts/delayed recovery. Reliable studies are used to compile recovery trajectories resulting in recovery durations for a range of habitats. These are presented in a step-wise framework for assessors to identify an appropriate recovery duration based on their chemical(s) of interest and types of habitats on and around their sites. Taking account of environmental recovery in an assessment is often neglected, but understanding the consequences of an accidental release is important to valuing the scale and severity of an impact. Recovery information could be used to direct appropriate management actions (as in COMAH/SEVESO) and avoid under- or overly-conservative compensatory actions in dealing with environmental damage and liability.

WEPC04

ECHA and communicating scientific content

T. Bräutigam; T. Multasuo, ECHA

ECHA is an Agency of the European Union with the responsibility to manage four pieces of European chemicals legislation: REACH, CLP, Biocidal Products Regulation (BPR) and PIC. The objective of all of them is to ensure a high level of protection of human health and the environment, as well as to enhance competitiveness and innovation of industry. The Agency needs to raise awareness and support duty holders – chemicals companies - in complying with the legislation. ECHA also needs to use the results of the legislative processes to promote the safe use of chemicals among downstream users, workers, consumers and other general audiences. This task requires content which explains the scientific data in an easily understandable way and in the relevant context. In order to achieve its communication objectives, ECHA needs to be realistic, strategic and consistent in its communication. The main communication principles are the following: Accessible. Communication vehicles are easily accessible, transparent and use understandable language. Strategic. ECHA focuses on defined priority topics and targets the key audiences. Reliable. ECHA's communication is accurate and predictable. Integrated. ECHA uses a variety of communication channels and vehicles to optimise the outreach and targeted messaging. EU level. ECHA's messages are targeted for audience segments but not for individual countries. Work with multipliers. ECHA engages EU level multipliers and member state competent authorities to enable targeted messaging and efficient outreach. Multilingual. Information intended for SMEs and general audiences is available in 23 EU languages. At SETAC, ECHA could present how it communicates scientific content to general public, covering different channels and modifying the content accordingly. This includes the use of ECHA's social media channels, audio-visual products and its dedicated web page to the general public, "Chemicals in our life". Regarding content, ECHA communicates regulatory matters but also content related to recent scientific developments, as nanomaterials, endocrine disrupters or alternatives to animal testing. ECHA also communicates directly with scientists, for example through organising topical scientific workshops and participating at events (SETAC, Eurotox). In addition, ECHA could present how it coordinated a risk communication network with the Member States and produced a guidance document on risk communication.

Post-modern times - The EcotoxBlog

J. Zubrod, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; M. Kraft, University of Koblenz-Landau / Welcome Center; K. Newton, University of Koblenz-Landau; V. Sesin, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; C. Bruehl, University of Landau, Institute for Environmental Sciences / Institute for Environmental Sciences; R.B. Schaefer, University of Koblenz-Landau / Institute for Environmental Sciences; K. Theissinger, University of Koblenz-Landau / Institute for Environmental Science; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences

Nowadays, communicating research results to 'outsiders' has become an essential part of academic activities with diverse goals that need to be met. These include raising public awareness about environmental issues, communicating science directly to the public or attracting students to universities. Taking advantage of social media can be an effective way to achieve these aims. As a part of a larger public outreach campaign of our university, we thus started the EcotoxBlog in May 2015 not only to improve public visibility of our Ecotoxicology-related research and our Master's program in Ecotoxicology, but also to foster internal communication and increase awareness of research-related activities. Since then, we regularly post summaries of our scientific work, written in non-technical language that is clear and comprehensible to a wide and potentially non-scientific audience. The summaries are comprised of the latest publications, novel projects, and updates about ongoing research in the various working groups. Moreover, we use the blog as a pin board to inform our students about all news related to their studies and future careers (e.g., job advertisements). The students welcome this new tool and we have recruited two student bloggers, who regularly write well-received contributions about their and their fellow students' experiences during the Master's course (e.g., lab courses or internships) as well as their first contacts with the scientific community (e.g., first scientific meetings). This blog is also an open platform to interact with colleagues and the larger public and anyone is free to contribute topically related tidbits of information. To draw the attention of irregular visitors to the EcotoxBlog, we also operate Facebook and Twitter accounts, where we advertise each blog post. Moreover, within the university, regular email newsletters inform staff and students about the latest posts, and everyone can subscribe to an RSS feed to receive all the news. Although only running for half a year now and still optimizing our posting strategies, the EcotoxBlog has proven to be an effective tool to communicate our research and the content of our study program to a diverse audience: lots of positive feedback and several hundred users per month from all over the world show that we are on the right track. So join us at http://www.master-ecotoxicology.de/ecotox-blog/.

WEPC06

Gamed-based tools as media to transmit freshwater ecology concepts

H. Serra, University of Bordeaux / Ecoloxicology unit; J. Raimbault, Ecole Polytechnique

There is an increasing expectation of people to be aware of the environmental issues; however, expert knowledge is often required to understand most of them. Thus, games could turn out to be a good medium for scientific vulgarization. Gamification has already been proposed as a tool for the propagation of scientific thinking. In this context, our project aims at developing game-based tools to transmit the basic concepts of freshwater ecology. We chose to focus on a classical board game and on a computer-based game because they are complementary in the targeted audience and the possibilities offered (interactions between players and the system dynamics). While the board game is inspired by past experiences of player, we propose to implement an agent-based model (ABM) for the computer version and to couple its dynamics with gaming actions. ABM have already been widely used in ecology, therefore, we selected a trophic chain dynamic model that captures species behavioral rules and spatially heterogeneous environment. We chose to represent the ecosystem from a fish perspective and to base both games on the same general rules. The player objective is to reach a given number of adults and juveniles that guarantee the stability of the fish population in a lake. For this purpose, each player has to find resources and to use them for different actions (e.g. reproduction). The perturbations of the ecosystem are illustrated by "events" designed to reflect abiotic (e.g. water temperature) and biotic (e.g. parasites, human) stressors. The current versions of the games include four players (fish species): roach, pumpkinseed, zander, and bleak. Our idea is to maximize the interactions between players (predation and competition) and to illustrate various feeding and reproduction strategies. A prototype of each game is currently available for testing and refinements are expected while testing the games. In a short term, the next versions will integrate the aesthetic design (edge of a lake) and refined processes parameters (model calibration). In a long term, we aim to develop an online version of the computer game and to use crowdfunding platforms to diffuse the board game. The very first objective of our games remains to be entertaining, keeping in mind that the ludic rather than educative aspects are central in such game-based media. If players forget that it is about ecology, it would mean that the underlying scientific concepts are understood, exactly what we want.

WEPC07

Heavy metal assessment in agricultural soils contributes to a sustainable information of the public regarding soil quality in a developing country

D. Sosa Pacheco, CENSA; D. Bürge, Agroscope ISS; I. Hilber, Agroscope ART; R. Faure Garcia, L. Aguiar Díaz, CENSA; T. Bucheli, Agroscope ART / Environmental Analytics Natural Resources and Agriculture; A. Escobar Medina,

Cuba is mainly an agricultural country and healthy food production depends on the quality of the soils. Several studies in Cuba propose reference values of heavy metals (HMs) indicating the quality of different soil types with little human activity. Nevertheless, systematic monitoring studies of HMs in soils of Cuba are scarce. Heavy metals are prone to be taken up by plants, which may affect food safety. To inform the stakeholders (consumers, farmers, government) about the quality of Cuban soils, a sound monitoring of contaminant exposure forms the base for an appropriate and adequate risk assessment, and corresponding communication with stakeholders. Our project Soil-Q, jointly carried out by the Cuban agricultural research institute CENSA and the Swiss Agroscope ISS aims to establish a monitoring network to assess the contamination status of Cuban soils. So, 39 sample locations with agricultural and rural character in the province of Mayabeque were monitored according to the rigorous protocol of the Swiss soil monitoring network. The mean concentrations of HMs (cadmium 2.6, chromium 63, copper 64, nickel 48, lead 16, zinc 55, and mercury 0.1 mg/kg_{soil}) measured in these sites do not exceed the intervention thresholds according to the regulations of Germany and Switzerland. However, the values higher than the median appeared in agricultural soils. Additionally, Soil-Q is to raise perception and awareness of the stakeholders. A film in the Cuban TV was shown and different workshops for representatives of related research and governmental institutes were held. The message was to inform about Soil-Q and that first results do not show a risk for humans and the environment. It is crucial to inform the general public as well as decision makers that this is only the beginning of a monitoring process that should extend over the whole country and over decades because soil is an important archive about human activities. Especially in a country where future changes are very likely, a long-term monitoring catching industrial and other human activities is of uttermost importance for the welfare of humans and the environment. It is a big challenge to maintain an information flow with projects that are finite. Public perception towards the quality of the environment, especially as there seems to be not an acute problem is very difficult to keep active. We hope therefore to learn more about this subject at this session by communicating and networking with other experts.

Endocrine Disruptors: Exposure, Hazard & Risk Assessment (PC)

WEPC08

When are risk assessments of endocrine disrupters scientifically sound and secure?

P. Matthiessen, Independent Consultant; A. Leopold, Independent Consultant/ Researcher / Wildlife International Ltd.; J. Odum, Regulatory Science Associates; M. Roberts, Independent Consultant / Chemicals   Emerging Technologies

The poster summarises the consensus that resulted from the SETAC Pellston™ Workshop: Environmental Hazard and Risk Assessment Approaches for Endocrine-Active Substances (EHRA), held at Pensacola on 31 January – 5 February 2016. The primary aim of the workshop was to provide objective advice, based on the current level of scientific understanding, to enable regulators/policy makers to make considered, informed decisions on whether to select a hazard- or a risk-based approach for a given endocrine-disrupting substance (EDS) under review. The workshop additionally considered recent developments in the identification of EDSs. All guidance developed was based on experience obtained from working on case histories of six data-rich endocrine-active substances (EAS) - ethinylestradiol, perchlorate, propiconazole, trenbolone, tributyltin and vinclozolin. This is a controversial subject because it is claimed by some that environmentally safe concentrations/doses of (certain?) EDSs cannot be established due to certain inherent properties *e.g.* unusual concentration/dose response curves; long-term effects resulting from short-term critical windows of exposure; difficulties of extrapolating to effects in untested life-stages and species *etc*. The implication is that such substances should be regulated solely on the basis of their intrinsic hazards. This poster summarises information on current best practice in the environmental hazard and risk evaluation of EDSs which was developed using a cross-section of international expertise on this issue. The core advice to regulators and policy-makers faced with a confirmed EDS is to ask a structured series of questions, as follows: Is exposure prediction reliable? Have relevant taxa and life stages been tested? Are tests adequate to detect delayed effects? Are tests likely to have missed adverse effects at concentrations below those tested? These questions are underpinned by detailed guidance on how they can be addressed, and at each stage, users are invited to fill in data-gaps as appropriate. Only if the required additional testing is not deemed feasible should regulation on the basis of hazard alone be considered until such time as suitable methodology becomes available. The overall conclusion of the EHRA SETAC Pellston Workshop™ was that if the questions above are adequately addressed, then conducting environmental risk assessment of EDSs is scientifically sound.

WEPC09

Uncertainties in biological responses that influence hazard or risk approaches to the regulation of endocrine active substances

J. Parrott, Environment Canada / Water Science and Technology Directorate; P. Bjerregaard, University of Southern Denmark / Department of Biology; C. Borgert, Applied Pharmacology & Toxicology, Inc.; K. Brugger, DuPont Crop Protection; L.E. Gray, U.S. EPA / ORDNHEERLRTD Endocrinology Branch; T. Iguchi, National Institute for Basic Biology / Molecular Environmental Endocrinology; S. Kadlec, University of Minnesota - Duluth / Integrated Biosciences; L. Weltje, BASF SE / Crop Protection   Ecotoxicology; J. Wheeler, Dow Agrosciences

Endocrine Disrupting Chemicals (EDCs) may have delayed or transgenerational effects and display non-monotonic dose response relationships (NMDRs) that require careful consideration when determining environmental hazards. The case studies evaluated for the SETAC Pellston Workshop™: Environmental Hazard and Risk Assessment Approaches for Endocrine-Active Chemicals and other key examples from the literature are discussed. EDCs can have specific and profound effects when exposure occurs over sensitive windows of the lifecycle (developmental, reproductive). This may induce delayed effects where the adverse effect is manifest at different lifestage(s). This underscores the need for testing in appropriate (sensitive) lifestages and full lifecycle designs that capture adverse effects wherever they occur in the lifecycle. Such tests are available in the toolbox and should be employed to derive endpoints that cover all life stage sensitivities. Similarly, the potential for effects to become manifest in subsequent generations (transgenerational) has also been raised as a potential issue in the derivation of appropriate endpoints for EDCs. However, the evidence for such effects as a general issue is limited. Indeed this is reflected in the design of new higher tier tests to assess EDCs developed under the auspices of the OECD and US-EPA by the move to extended one-generation designs and away from multi-generational studies for fish and mammals. The occurrence of non-monotonic dose or concentration response relationships is also considered a limiting factor for reliable risk assessment of EDCs. Substantial data reviews are underway to inform on their occurrence and relevance. However, evidence to date indicates they are more prevalent in *in vitro* and *in vivo* mechanistic data, not often translating to adverse apical endpoints that would be employed in risk assessment. A proposal of how to evaluate NMDRs in the context of endocrine hazard and risk assessment procedures is presented. If careful consideration of delayed, transgenerational and NMDR effects is made, it is feasible to assess environmental endocrine hazards and derive robust endpoints for risk assessment procedures ensuring a high level of environmental protection.

WEPC10

Assessing the Effects of Endocrine-active Substances on Populations

S. Marty, Dow Chemical Company; A. Blankinship, U.S. Environmental Protection Agency; J. Chambers, Mississippi State University; L.A. Constantine, Pfizer, Inc. / Pharmacokinetics Dynamics and Metabolism; W. Kloas, Leibniz-Institute of Freshwater Ecology and Inland Fisheries; A. Kumar, CSIRO / Center for Environmental Contaminants Research; L. Lagadic, Bayer CropScience / Environmental Safety; J. Meador, NOAA Fisheries; D. Pickford, Syngenta UK Ltd.; T. Schwarz, Centre for Environment, Fisheries, and Aquaculture Science; T.A. Verslycke, Gradient

For ecotoxicological risk assessment, endocrine disrupters require: 1) mechanistic information to demonstrate an endocrine mode-of-action (MoA), and 2) a plausible linkage between this MoA and an adverse effect that is relevant at the population level (WHO IPCS, 2002). In establishing MoA, data on additional endpoints (subcellular-through-organ levels) are collected for different taxa, but their link to adverse population level effects is often unclear. Case studies of endocrine-active substances (EAS) (tributyltin, ethinyl estradiol, perchlorate, trenbolone, and vinclozolin) were used to evaluate the population relevance of toxicity endpoints for use in hazard and risk assessment. The data for various taxa (invertebrate, fish, amphibian, avian, and mammalian) were examined using the OECD Conceptual Framework for Testing and Assessment of Endocrine

Disrupters to determine the relevance to adverse, population level effects. For some EAS like tributyltin, population relevance of mollusk imposex is well established. In fish, altered secondary sex characteristics by vinclozolin did not affect reproduction in a medaka extended one-generation study, and were judged to be not relevant for fish populations. Higher concentrations of vinclozolin decreased reproduction in fish, which is population relevant. The amphibian metamorphosis assay can detect altered stage distribution of tadpoles, which is predictive of increased time to complete metamorphosis, and might result in adverse effects for amphibian populations. In birds, population-relevant endpoints include egg production, hatchability, embryo viability, growth and egg condition. Decreased tibia-femur length (i.e., growth) in developing birds was seen with the thyroid-active compound, perchlorate. In mammals, anti-androgens like vinclozolin can affect reproductive development (e.g., decreased anogenital distance, nipple retention), but the population relevance of these endpoints is uncertain. In longer-term studies, vinclozolin reduced male rat fertility and successful mating, effects that are population relevant. Recovery processes also are important when evaluating the adverse effects of EAS on wildlife populations. Lastly, new methodologies (e.g., adverse outcome pathways - AOP and modelling) will aid in our understanding of endocrine perturbations and adverse population level effects once our knowledge on key event relationships improves.

WEPC11

Current limitations and a path forward to improve testing for the environmental assessment of endocrine active substances

K.K. Coady, The Dow Chemical Company / Toxicology Environmental Research and Consulting; R.C. Biever, Smithers Viscient / Dept of Environmental Toxicology; N.D. Denslow, University of Florida / Physiological Sciences; M. Gross, WCA Environment; P.D. Guiney, Retired- S C Johnson & Son, Inc / Molecular and Environmental Toxicology Center; H. Holbech, University of Southern Denmark / Department of Biology; N.K. Karouna-Renier, USGS Patuxent Wildlife Research Center / Beltsville Lab; I. Katsiadaki, Centre for Environment Fisheries and Aquaculture Science / Environment and Animal Health; H.O. Krueger, Wildlife International / Aquatic Plant and Insect Toxicology; S.L. Levine, Monsanto Company / Global Regulatory Sciences; G. Maack, Federal Environment Agency / Ecotoxicological Assessment; M. Williams, CSIRO / Land and Water; J.C. Wolf, Experimental Pathology Labs., Inc.; G.T. Ankley, U.S. EPA / National Health and Environmental Effects Research Laboratory

To assess the hazards and risks of possible endocrine active chemicals (EACs) there is a need for robust, validated test methods that detect perturbation of endocrine pathways of concern and provide insights reliable information as to assess to potential adverse effects on apical endpoints. One issue of significant concern to for current EACS screening/testing programs involves resources in regard such as to cost, time, trained personnel, and animal use. This is especially problematic when considering the number of chemicals that some regulatory authorities need to assess. One way to address this challenge is to prioritize chemicals for possible *in vivo* testing using *in vitro* high throughput (HTP) assays focused on a suite of endocrine molecular initiating events (MIEs) of concern. Additional challenges associated with the design and conduct of *in vivo* EAC screening and testing include selection of appropriate species (*i.e*., sensitive and amenable to laboratory testing), endpoints and life-stages. A component of this involves experience gained using existing tests to determine, for example, those that have been shown to be exceptionally sensitive to perturbation of a given MIE of concern. However, there is the opportunity for strategic use of HTP data and/or early screening level information to help guide the selection of existing assays that can further evaluate a given EAC modality. Further challenges for EAC screening and testing involve guidance and optimization in several areas, such as concentration setting, statistical power to detect biologically significant adverse effects, delivery and analytical measurement of test substances, availability of technical expertise, and study interpretation, including linking mechanistic and apical effects. Some of these areas can be addressed by the lessons learned and best practices developed through recent experiences conducting EAC screening/testing. Additionally, the collective assessment of EAC screening and testing data (*e.g*. compilation of historical control data) can be leveraged to refine test designs and performance criteria to maximize the power and utility of EAC screening/testing. Finally, a number of recommendations are provided for longer term research to address areas of uncertainty, including identifying potentially sensitive species for which test methods currently do not exist (*e.g*., invertebrates) and key endocrine pathways in addition to estrogen, androgen and thyroid signalling.

WEPC12

Challenges in Assigning Endocrine Specific Modes of Action: Recommendations for Researchers and Regulators

E.M. Mihaich, ER2; C. Schaefers, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / Ecotoxicology; D.A. Dreier, University of Florida / Physiological Sciences; M. Hecker, University of Saskatchewan / School of the Environment and Sustainability and Toxicology Centre; L.S. Ortego, Bayer CropScience / Environmental Toxicology and Risk Assessment; Y. Kawashima, Japan NUS Co.; Z. Dang, RIVM; K.R. Solomon, University of Guelph / School of Environmental Sciences

As regulatory programs focus on evaluating substances for their endocrine disrupting properties, there is a need for careful study design and data interpretation to distinguish between endocrine versus non-endocrine specific responses. This is particularly important where specific criteria are under development to identify endocrine disrupting properties to enable hazard-based regulation. Irrespective of the regulatory process, most jurisdictions use the WHO IPCS definition of an endocrine disruptor (ED), requiring that a substance is demonstrated to cause a change in endocrine function that consequently leads to an adverse effect in an intact organism. Such a definition is broad, and might capture mechanisms that in general can be both, substance specific and substance-non-specific endocrine responses. For instance, stress is a non-specific, neuro-endocrine response that can lead to adverse outcomes. In addition, non-endocrine toxic mechanisms (e.g. hepatotoxicity, acetylcholinesterase inhibition) may operate secondarily or in parallel to impact the endocrine system and apical endpoints downstream. Furthermore, endocrine responses may be adaptive in nature and designed to maintain homeostasis rather than inducing an irreversible adverse effect. The likelihood of indirect effects is increased in (eco)toxicological studies requiring the use of maximum tolerated dose levels, which must produce some adverse effect. The misidentification of indirect effects as truly ED has serious consequences in terms of triggering animal and resource intensive testing and potentially severe regulatory consequences. A review, based on 6 case study substances, was conducted to evaluate scenarios that could complicate the assessment of whether or not a substance is an endocrine disruptor. In order to achieve this objective, a weight of evidence approach was used to evaluate available data for the case-study substances. In this approach, the weight of evidence was based on biological plausibility, empirical support, and essentiality of key events in adverse outcome pathways. A process is recommended where indicative (endocrine specific and non-endocrine specific) and apical endpoints can be evaluated to investigate whether an endocrine mode of action can be conclusively assigned to the effects observed for a given substance. Two examples are discussed each with varying degrees of endocrine mode action specificity.

Evaluating the Credibility of Histopathology Data in Environmental Endocrine Toxicity Studies

J.C. Wolf, Experimental Pathology Labs., Inc.; G. Maack, Federal Environment Agency / Ecotoxicological Assessment

Agencies responsible for environmental protection are tasked with developing regulatory guidance that is based on the best available scientific evidence. Histopathology is a common endpoint in toxicological bioassays, and advantages of this endpoint for ecotoxicological research include: (i) reasonably high degrees of sensitivity and specificity relative to other endpoints; (ii) the ability to identify and/or confirm novel or unanticipated treatment effects that may not be detected by other means; (iii) the ability to reveal the presence of subclinical (and potentially confounding) background disease; (iv) the ability to link effects obtained from molecular or *in vitro* experiments to more apical population-relevant endpoints; and (v) in some cases, the provision of key mechanistic information pertaining to toxicity. However, because of the subjective nature of histopathology, and the advanced level of specialized training required for the effective utilization of this endpoint, the reliability of histopathology data can be inconsistent. Consequently, mechanisms for evaluating such data on a case-by-case basis are needed. The purposes of this report are to describe methodology that can be used to evaluate the credibility of histopathology findings in published articles, and discuss the results of such assessments as applied to real-world data gathered from the scientific literature. The ultimate goals of this work are to draw attention to reliability issues that can affect the histopathology endpoint, provide recommendations to improve the quality of this endpoint, and suggest an approach for the expeditious and judicious use of histopathology data in weight of evidence determinations required for hazard and/or risk assessment. This exercise was conducted initially as part of a SETAC-Pellston Workshop™ entitled "Environmental Hazard and Risk Assessment Approaches for Endocrine-Active Chemicals (EHRA): Developing Technical Guidance Based on Case Studies to Support Decision Making" that was held in Pensacola, Florida, USA, from January 31st to December 5th, 2016.

Passive sampling of organic micropollutants and toxicity assessment: opportunities, challenges and innovations (PC)

A comparison between passive samplers and bioassays to monitor the release of produced water from the oil and gas industry in the water column

S. Hale, NGI; A. Oen, G. Cornelissen, Norwegian Geotechnical Institute; M.T. Jonker, Utrecht University; E. Eek, NGI / Environmental Technology

In 2012, the total production of oil and gas in Norway represented 226 million cubic meters of oil equivalent. Produced water (PW) represents the largest volume waste stream in oil and gas production operations from most offshore platforms. In 2012, around 130 million cubic meters of PW was discharged by the

Norwegian offshore oil and gas industry. PW includes both formation water (seawater or freshwater trapped with oil and gas in a geological reservoir) and injected water (seawater, freshwater and brine water as well as added chemicals that are injected to enhance recovery of oil and gas, and operational safety) and as such contains components such as dispersed oil, aromatic hydrocarbons, alkylphenols, organic acids, heavy metals, radioactive materials and inorganic salts. The exploration of oil and gas takes place offshore in sensitive coastal environments and as such stringent monitoring regulation must be followed. The currently used water column monitoring strategy includes the use of passive samplers and caged organisms to monitor the effects of releases of PW. Passive samplers and caged organisms must be placed on all monitoring stations and passive samplers should be used to monitor dispersal of discharge to the environment. This work investigated the relationship between monitoring results obtained via the use of passive samplers and organisms using a real PW sample as a case study. Four passive samplers (polyethylene, polyoxymethylene, polyethersulfone and polydimethylsiloxane) were calibrated for PAHs and alkylated PAHs by determining respective passive sampler-water partitioning coefficients. A small field deployment in the Oslo fjord was carried out to investigate ease of deployment. Polyethylene and polydimethylsiloxane were identified as the most optimal passive samplers monitoring chemicals in PW. Polyethersulfone did not function as an equilibrium passive sampler, as expected, and was very difficult to deploy as a single membrane in the field. A battery of bioassays were then carried out in using the PW sample and also extracts from the selected passive samplers that had been exposed to the PW sample. In addition the PW was diluted to simulate increased distance from the release point and the bioassays were carried out again. The correlation between concentrations determined with passive samplers and the ecotoxicological response to the organisms will be investigated.

WEPC15
Assessing the toxic potential of river water by combining passive sampling with bioassays
B. Becker, German Federal Institute of Hydrology; A. Duffek, German Environment Agency; P. Lepom, German Environment Agency / Laboratory for Water Analysis; S. Buchinger, Federal Institute of Hydrology / Department G Biochemistry Ecotoxicology; C. Möhlenkamp, E. Claus, Federal Institute of Hydrology / Department Biochemistry and Ecotoxicology; S. Schaefer, Federal Institute of Hydrology / Biochemistry Ecotoxicology
Bioanalytical tools can provide important information on the toxic potential of complex chemical mixtures of environmental samples and are, therefore, complementary to chemical analysis. The combination of passive sampling with bioassays is a promising approach for assessing water quality as 1) passive samplers accumulate a broad spectrum of chemicals while excluding most of the matrix and 2) chemicals with the same mode of toxic action are detected in parallel. Up to now, the majority of studies investigated solvent extracts of polar organic integrative chemical samplers with the yeast estrogen screen (YES) to assess contamination of aquatic environments with chemicals causing estrogen-like activity[1]. To study the toxic potential of river water, silicone-based samplers were exposed in rivers for five weeks, extracted with n-heptane in a Soxhlet-apparatus and then extracts were tested in bioassays. In preliminary experiments, extracts from passive sampler that had been exposed in the rivers Rhine, Danube, Elbe, Saale and Saar were tested in bioassays measuring mutagenic (Ames fluctuation assay) and endocrine activity (YES). Thereby, samples from the river Saar showed high mutagenic potential in the Ames fluctuation assay, in particular when using the strain YG 1041 that is sensitive to nitroaromatic compounds and, after metabolic activation by S9-mix to aromatic amines. Therefore, a more comprehensive monitoring program was conducted along the river Saar in 2015, whereby passive samplers were exposed at twelve sampling sites in the river Saar, its main tributaries, and in the effluent of a wastewater treatment plant. All samples showed mutagenic potential with highest effects in samples from sites located in the Saarland conurbation, an important old-industrialised region in Germany, as well as in samples from the main tributaries. In most cases, mutagenic effects were detected after metabolic activation with S9 mix, whereas no or only minor mutagenic potential were found without metabolic activation. This indicates that the mutagenic potential might primarily result from aromatic amines and not from nitroaromatic compounds.\n

Screening methods for fate and toxicity of produced waters
E. Michie, Shell International / Shell Health Risk Science Team; C.V. Eadsforth, Shell International / Shell Health; G. Whale, Shell Health / Shell Health; T. Halmans, Shell Global Solutions International / Anakytical Department; A. van der Laan, Shell Global Solutions International / Analytical
There is a need to improve the risk assessment of offshore produced water (PW) discharges and find a rapid and cost effective alternative to logistically challenging WET testing. A simple battery of monitoring techniques, which closely mirrors the OSPAR Risk Based Approach (RBA), has been trialled in a wide range of facilities. This study has applied solid phase micro-extraction coupled with gas chromatography (SPME-GC), a biomimetic technique, and the *in-vitro* Microtox assay (*Vibrio fischeri* bioluminescence assay) for the purpose of produced water toxicity assessment. These techniques will ultimately form part of a toolbox for early tier routine screening of produced water effluents. A collection programme of PW samples was coordinated from a number of offshore PW waste streams. Aliquots were simultaneously tested using Microtox to describe the toxicity of both known and unknown components, and SPME-GC to determine the soluble, and thus bioavailable, hydrocarbon concentration. Components desorbed from the fibre were quantified as total dissolved petroleum hydrocarbon concentration, by calibration against hydrocarbon standards. Toxicity (assessed using Microtox) increases in line with dissolved hydrocarbons determined by SPME-GC suggesting hydrocarbon contamination to be a major contributor to toxicity. Biomimetic techniques such as SPME will also reflect the potential of a substance to bioaccumulate and thus provides more ecologically relevant data. Initial BCF testing has demonstrated bioaccumulation potential of PW to be of low concern. In due course, Microtox and SPME-GC screening will assist with other screens in PBT determination, fulfilling Step 2 of the RBA by providing toxicity and bioaccumulation data.

Many components of complex organic pollutant mixtures in waters are often present at very low levels, posing a challenge for current analytical methods. Passive sampling is one of the perspective methods that could address this problem. In our work, we used a mobile "active" passive sampling system with two types of sorbent (EMPORE discs, silicone rubbers), which preconcentrates a wide spectrum of polar and non-polar organic pollutants from the water column. Eight Danube river stretches were sampled and spatial distribution profiles were described for a comprehensive range of organic pollutants including pesticides, pharmaceuticals and industrial chemicals. Sampling rate and the original concentrations of the pollutants in water were estimated for pollutants with different physicochemical properties by a set of reference compounds. The employed mode of passive sampling with an active exchange of water in the sampling chamber proved to be about five-times more effective than static exposure and in relatively short sampling times allowed quantification of chemicals in pg.L^{-1} levels. Beside chemical analyses, samples were characterized with a battery of *in vitro* bioassays sensitive to chemicals with selected modes of action. Toxic potentials for causing endocrine disruption (anti/estrogenic, anti/androgenic), dioxin-like activity, pregnane X receptor (PXR)-mediated activity and oxidative stress-associated response showed spatial variation along the river. Polarity of chemicals played an important role, while AhR-mediated effects were associated mostly with non-polar compounds (sampled by the silicone rubber sampler) the rest of toxic potentials was associated mainly with more polar chemicals sampled by the EMPORE disc samplers. To link the toxic potentials with chemical analysis data, the detected pollutant levels and their relative effect potencies were used for calculation of bioanalytical equivalent concentrations (BEQs) using the concentration addition concept, with effect concentrations obtained from literature or US EPA ToxCast database. BEQs served for explaining the observed bioassay-derived toxic potentials and identification of the main drivers of toxicity. Our work demonstrates the utility of passive sampling for analysis of trace contaminants in river water as well as effect-based monitoring. The SOLUTIONS Project is supported by the Seventh Framework Programme (FP7-ENV-2013) of the European Union under grant agreement no. 603437.

WEPC18
COMPLEMENTARITY OF PASSIVE SAMPLERS AND PASSIVE BIO-MONITORING TO EVALUATE SURFACE WATER CONTAMINATION BY PESTICIDES IN VINEYARD CATCHMENT
M. Le-Dréau, C. Margoum, Irstea Lyon / Laboratory for chemical analyses of aquatic environments; A. Martin, Irstea / Laboratory for chemical analyses of aquatic environments; S. Pesce, Irstea Lyon / Microbial ecology of anthropised river systems; V. Gouy, Irstea Lyon / Diffuse agricultural pollution

Grab sampling may be scarcely adequate to evaluate the impact on surface waters of pesticide used in agriculture because of its poor spatiotemporal representativeness compared to the high variability of the contamination patterns. Indeed, it is still not easy to link the effect of agricultural practice changes to water quality at the catchment scale. Furthermore, biological indicators may also be useful in addition to pesticide concentration determination to evaluate their impact on ecosystems. In this way, the contribution of new integrative tools has been evaluated. Passive samplers and biological indicators have been applied together at the catchment scale so as to identify their coherence and complementarity. The tested chemical tool is the Silicone Rod (SR) dedicated to hydrophobic to moderately hydrophilic compounds. In total, 22 pesticides (12 herbicides, 5 fungicides and 5 insecticides) were analyzed as well as potential confusing parameters (metal(oïd)s, nutrients, temperature). In parallel the biological approach consisted in an *in situ* study of i) leaf litter decomposition processes, which are mediated by the combined action of microbial and invertebrate communities and of ii) the measurement of fungal biomass within leaf-associated microbial communities. These tools have been applied during June 2014 and June 2015 (corresponding to a period of pesticides application on vineyard) in Ardières river. The Ardières basin, situated in the Beaujolais region (France), is submitted to viticulture pressure and a marked pesticide contamination has already been highlighted. Three measurement stations have been chosen along the contamination gradient from upstream to downstream. Results showed the high coherence of chemical and biological tools responses. All of them were able to reflect the spatial contamination gradients as well as the specific contamination and impact associated. Thus, decomposition rates and fungal biomass decreased from up to downstream, in relation to the observed increase in fungicides and organophosphorus insecticides concentrations. This biological impact was observed during the two years studied, while pesticide contamination decreased in 2015 compared to 2014. Finally, their sensitivity, reactivity and integration capacity make these tools relevant and promising to assess agricultural pesticide impact on surface water in addition to grab sampling.

From in-situ passive sampling into bio assays - an innovative approach of combined chemical and biological analysis of HOCs

H. Hercht, RWTH Aachen / Department of Ecosystem Analysis; N.C. Niehus, Hamburg University of Applied Sciences HAW / Department of Environmental Engineering; T. Seiler, RWTH Aachen University / Ecosystem Analysis; H. Hollert, RWTH Aachen University / Department of Ecosystem Analysis; H. Witters, VITO / Applied Bio   molecular Systems

The proposed project aims at the development of innovative indicators to allow for a spatially structured description and assessment of the pollution and the risk potential of sediment-bound contaminants in marine ecosystems. For the first time the project will obtain toxicity data for the pore water concentrations of pollutants with largely reduced uncertainty, directly correlate the results with chemical analysis and verify the findings using artificial mixtures of the target analytes. This will be achieved by adaptation of an in situ equlibrium sampler (passive sampler) based on solid phase microextraction (SPME) for the investigation of hydrophobic organic compounds in marine ecosystems. The PDMS hollow fibers carrying the sampled pollutant mixtures will then be directly applied as passive dosing phases in small-scale biotest systems. As hence no extraction of the fibers is necessary, the risk to alter the original substance composition is significantly reduced. Thus, resulting data are highly representative for the actual pollution on-site. Subsequently, the analysed mixture will be reassembled and tested with concentration series using passive dosing in the test systems to derive concentration-response curves. Together with results on the distribution and accumulation of the contaminants an estimation of the risk due to sediment-bound pollutants will be possible (mixture toxicity). Such realistic toxicity data in combination with knowledge on the distribution of the compounds and correlated with sediment parameters are a good foundation to derive reliable indicators for a good environmental state of Baltic Sea waters.

The Society of Environmental Toxicology and Chemistry (SETAC) is a not-for-profit, global professional organisation comprised of some 5500 individual members and institutions dedicated to the study, analysis and solution of environmental problems, the management and regulation of natural resources, research and development, and environmental education. SETAC Europe is one of the five Geographic Units of the global Society, established to promote and undertake activities of SETAC in Europe, and to support activities of SETAC in the Middle East and Africa. The Society is dedicated to the use of multidisciplinary approaches to examine the impacts of stressors, chemicals and technology on the environment. We also provide an open forum for scientists and institutions engaged in the study of environmental problems, management and regulation of natural resources, education, research and development, and manufacturing. SETAC Europe is incorporated in Belgium as a not-for-profit organisation. The Society is governed according to its articles of association and by-laws. SETAC Europe maintains its administrative office in Brussels, Belgium.
